

STATE GAME COMMISSION MEETING AND RULE MAKING NOTICE

The New Mexico State Game Commission (“Commission”) will be hosting a meeting and rule hearing on Friday October 27, 2023 beginning at 9:00 a.m. at the Farmington Civic Center, 200 W. Arrington St., Farmington, NM 87401. The purpose of this meeting is to hear and consider action as appropriate on the presentation of proposed changes to the Bear and Cougar Rule 19.31.11 NMAC.

Synopsis

The proposal is to amend the Bear and Cougar Rule 19.31.11 NMAC which will become effective April 1, 2024. The most recent version of the rule will expire on March 31, 2024.

PROPOSED CHANGES TO THE BEAR AND COUGAR RULE

Allow licensed deer or elk hunters who draw WMA hunts to harvest a bear or cougar during their hunt if the zone is open and they possess a Bear and/or Cougar License.

Bears

- Increase bear harvest limits in BMZs 1 and 10 based on population estimates from new NMDGF research from 2019-2021;
- Adjust BMZs 5, 6, and 7 such that GMU 57 will be moved from BMZ 7 into BMZ 5, and GMUs 56 and 58 will be moved from BMZ 7 into BMZ 6, thus dissolving BMZ 7 into those zones. Harvest limit allocations from those GMUs in previous BMZ 7 will be re-allocated to the new BMZs of which they are a part;
- Increase number of permits for bear draw permit BER-1-104 from 32 permits to 60 permits to increase opportunity. Draw hunters will still be subject to the existing harvest limit structure;
- Increase number of permits for bear draw permit BER-1-103 from 5 permits to 10 permits, in recognition of the expanded hunt area resulting from the Department’s acquisition of the LBar property. Draw hunters will still be subject to the existing harvest limit structure;
- Move the season start date for BMZs 12 and 13 from September 1st back to August 16th.

Cougars

Reduce harvest limits for CMZ Q based on research studies and statistical modelling efforts.

A full text of changes for all rules will be available on the Department’s website at: www.wildlife.state.nm.us.

Interested persons may submit comments on the proposed changes for the Bear and Cougar Rule to: DGF-Bear-Cougar-Rules@state.nm.us. Individuals may also submit written comments to the physical address below. Comments are due by 1:00 p.m. on October 25, 2023. The final proposed rules will be voted on by the Commission during a public meeting on October 27, 2023. Interested persons may also provide data, views or arguments, orally or in writing, at the public rule hearings to be held on October 27, 2023.

Full copies of text of the proposed new rules, technical information related to proposed rule changes, and the agenda can be obtained from the Office of the Director, New Mexico Department of Game and Fish, 1 Wildlife Way, Santa Fe, New Mexico 87507, or from the Department’s website at www.wildlife.state.nm.us/commission/proposals-under-consideration/. This agenda is subject to change up to 72 hours prior to the meeting. Please contact the Director’s Office at (505) 476-8000, or the Department’s website at www.wildlife.state.nm.us for updated information.

If you are an individual with a disability who is in need of a reader, amplifier, qualified sign language interpreter, or any other form of auxiliary aid or service to attend or participate in the hearing or meeting, please contact the Department at (505) 476-8000 at least one week prior to the meeting or as soon as possible. Public documents, including the agenda and minutes, can be provided in various accessible formats. Please contact the Department at 505-476-8000 if a summary or other type of accessible format is needed.

Legal authority for this rulemaking can be found in the General Powers and Duties of the State Game Commission 17-1-14, et seq. NMSA 1978; Commission's Power to establish rules and regulations 17-1-26, et seq. NMSA 1978.

TITLE 19 NATURAL RESOURCES AND WILDLIFE
CHAPTER 31 HUNTING AND FISHING
PART 11 BEAR AND COUGAR

19.31.11.1 ISSUING AGENCY: New Mexico department of game and fish.
[19.31.11.1 NMAC - Rp, 19.31.11.1 NMAC, 4/1/2024]

19.31.11.2 SCOPE: Sportspersons interested in bear and cougar management and hunting. Additional requirements may be found in Chapter 17 NMSA 1978 and Title 19 NMAC.
[19.31.11.2 NMAC - Rp, 19.31.11.2 NMAC, 4/1/2024]

19.31.11.3 STATUTORY AUTHORITY: 17-1-14 and 17-1-26 NMSA 1978 provide that the New Mexico state game commission has the authority to establish rules and regulations that it may deem necessary to carry out the purpose of Chapter 17 NMSA 1978 and all other acts pertaining to protected mammals, birds, and fish.
[19.31.11.3 NMAC - Rp, 19.31.11.3 NMAC, 4/1/2024]

19.31.11.4 DURATION: April 1, 20202024 through March 31, 20242028.
[19.31.11.4 NMAC - Rp, 19.31.11.4 NMAC, 4/1/2024]

19.31.11.5 EFFECTIVE DATE: April 1, 20202024, unless a later date is cited at the end of a section.
[19.31.11.5 NMAC - Rp, 19.31.11.5 NMAC, 4/1/2024]

19.31.11.6 OBJECTIVE: Establishing open hunting seasons and regulations, rules and procedures governing the distribution and issuance of bear and cougar licenses and permits by the department.
[19.31.11.6 NMAC - Rp, 19.31.11.6 NMAC, 4/1/2024]

19.31.11.7 DEFINITIONS:

- A. “Bear entry permit”** shall mean a permit awarded through a public drawing which entitles the holder of an over-the-counter bear license to hunt in a limited entry area during season dates established in rule.
 - B. “Bear zones”** shall define-mean hunt areas consisting of one or more game management units as described in 19.30.4 NMAC.
 - C. “Cougar zones”** shall define-mean hunt areas consisting of one or more game management units as described in 19.30.4 NMAC.
 - D. “Department”** shall mean the New Mexico department of game and fish.
 - E. “Director”** shall mean the director of the New Mexico department of game and fish.
 - F. “Game management unit” or “GMU”** shall mean those areas as described in 19.30.4 NMAC.
 - G. “Wildlife management areas” or “WMAs”** shall mean those areas as described in 19.34.5 NMAC.
- [19.31.11.7 NMAC - Rp, 19.31.11.7 NMAC, 4/1/2024]

19.31.11.8 ADJUSTMENT OF LICENSES, PERMITS AND HARVEST LIMITS:

- A. The director, with verbal concurrence of the chairperson or their designee, may adjust the number of licenses, permits or harvest limits, up or down by no more than twenty percent within a bear zone or cougar zone, to address critical department management needs, significant changes in population levels or habitat availability. This adjustment may be applied for bear and cougar within the specified zones to any or all of: the specific hunt codes; total harvest limits; or female harvest sub-limits.**
 - B. The director, with verbal concurrence of the chairperson or their designee, may take management actions independent of seasons and restrictions, harvest limits or female sub-limits for population management, or to address critical situations including ungulate population protection, depredation, human health and safety or other wildlife management issues. The decision to take management actions pursuant to this subsection shall be reported to the commission.**
- [19.31.11.8 NMAC - Rp, 19.31.11.8 NMAC, 4/1/2024]

19.31.11.9 BEAR AND COUGAR LICENSE APPLICATION REQUIREMENTS AND RESTRICTIONS:

~~A. Bear entry hunt: It shall be unlawful to hunt bear in designated wildlife management areas or other specifically designated special entry hunt areas without having a valid bear entry permit and a valid bear license in the hunter's possession or as otherwise allowed by game commission rule. Bear entry hunters shall be allowed to hunt in any other open bear zone provided they have a valid bear license.~~

~~B. Mandatory cougar identification course: All persons shall complete the mandatory cougar identification course offered on the department's website prior to purchasing a cougar license.~~
[19.31.11.9 NMAC - Rp, 19.31.11.10 NMAC, 4/1/2020]

19.31.11.9 [RESERVED]

[19.31.11.9 NMAC - Repealed, 4/1/2024]

19.31.11.10 BEAR AND COUGAR ZONE CLOSURES, BAG LIMITS AND AREA CLOSURES RESTRICTIONS:

A. **Zone closures:** Bear and cougar may be hunted or taken only in zones designated as open on the department hotline or website. Zones will close within 72 hours of when the reported number of bears or cougars harvested is within ten percent of the total limit or female sub-limit for that zone, whichever occurs first.

B. **Bag limit:** The bag limit for bear is one; the bag limit for cougar is two. It is unlawful to kill a bear sow with cub(s) or any bear cub less than one year old, or to kill a spotted cougar kitten or any female cougar accompanied by spotted kitten(s).

C. ~~Areas closed to bear and cougar hunting~~ **Limited entry hunt areas:** ~~It shall be unlawful to hunt bear or cougar in designated WMAs or other specifically designated special entry hunt areas with the following exceptions:~~

(1) ~~Legally licensed bear hunters possessing a valid bear entry hunt permit may hunt bears in the area(s) specified on the permit, or as otherwise allowed by rule. Bear entry hunters shall be allowed to hunt in any other open bear zone provided they have a valid bear license.~~

(2) ~~Legally licensed deer and elk hunters whose license is valid on a WMA or the Valle Vidal and are in possession of a valid over-the-counter bear or cougar license, may hunt bear or cougar in the WMA or the Valle Vidal as specified on their deer or elk license. Deer or elk hunters choosing to hunt bear or cougar under this provision may not use dogs, may hunt only in open bear or cougar zones, and must adhere to the weapon type restriction and season dates as specified by their deer or elk licenses.~~

D. Cougar hunting requirements and restrictions:

(1) ~~All persons shall complete the mandatory cougar identification course offered on the department's website prior to purchasing a cougar license.~~

(2) ~~Cougar hunting is closed in the Florida mountains hunt area during any open Persian ibex season, except by legally licensed Persian ibex hunters in possession of a valid cougar license. Persian ibex hunters may hunt cougar only if the cougar zone is open, and must adhere to the weapon type restrictions and season dates as specified by their Persian ibex license.~~

~~C. Areas closed to bear and cougar hunting: Limited entry hunt areas listed in 19.31.11 NMAC are closed to over the counter bear hunters who do not possess an entry permit. Cougar hunting in these areas is allowed only by licensed deer or elk hunters in possession of a valid cougar license in the E.S. Barker, Colin Neblett, Humphries, Marquez, Sargent, and Urraca WMAs, and the Valle Vidal. Deer or elk hunters choosing to hunt cougar under this provision may not use dogs, may only hunt in open cougar zones, and must adhere to the weapon type restriction and season dates as specified by their deer or elk licenses. Cougar hunting is closed in the Florida mountains hunt area during any open Persian ibex season, except by legal Persian ibex hunters in possession of a valid cougar license. Persian ibex hunters may only hunt cougar if the cougar zone is open, and must adhere to the weapon type restrictions and season dates as specified by their Persian ibex license.~~

[19.31.11.10 NMAC - Rp, 19.31.11.10 NMAC, 4/1/2024]

19.31.11.11 BEAR HUNTING SEASONS:

A. **Over-the-counter bear hunts for the 2020-212024-25 through 2023-242027-28 seasons:** The following table lists bear zones, open GMUs, ~~weapon type sporting arm~~ restrictions, season dates, total harvest limits, and female harvest sub-limits.

Bear zone	open GMUs or areas	bow only	any big game sporting arms	2020-24 2024-25 total limit (female)	2021-22 2025-26 total limit (female)	2022-23 2026-27 total limit (female)	2023-24 2027-28 total limit (female)

Specific statutory or other authority authorizing rulemaking:

Notice date(s):

Hearing date(s):

Rule adoption date:

Rule effective date:

Concise Explanatory Statement For Rulemaking Adoption:

2023 NOV -9 AM 8:29

Findings required for rulemaking adoption:

Findings MUST include:

- Reasons for adopting rule, including any findings otherwise required by law of the agency, and a summary of any independent analysis done by the agency;
- Reasons for any change between the published proposed rule and the final rule; and
- Reasons for not accepting substantive arguments made through public comment.

The rulemaking was undertaken to adopt a new Bear and Cougar Rule, 19.31.11 NMAC, which will become effective April 1, 2024. The current Bear and Cougar Rule will expired on March 31, 2024.

The new rule will include:

Statewide Changes

Allow licensed deer or elk hunters who draw WMA hunts to harvest a bear or cougar during their hunt if the zone is open and they possess a Bear and/or Cougar license.

Bear

- 1) Increase bear harvest limits based on population estimates from new NMDGF research from 2019-2021 in BMZs 1 and 10;
- 2) Adjust BMZs 5, 6, and 7 such that GMU 57 is moved from BMZ 7 into BMZ 5, and GMUs 56 and 58 is moved from BMZ 7 into BMZ 6, thus dissolving BMZ 7 into those zones. Harvest limit allocations from those GMUs in previous BMZ 7 are re-allocated to the new BMZs of which they are a part;
- 3) Increase number of permits for bear draw permit BER-1-104 from 32 permits to 60 permits to increase opportunity. Draw hunters are still subject to the existing harvest limit structure;
- 4) Increase number of permits for bear draw permit BER-1-103 from 5 to 10 permits, in recognition of the Department's acquisition of the LBar property. Draw hunters are subject to the existing harvest limits;
- 5) Move the season start date for BMZs 12 and 13 from September 1st back to August 16th.

Cougar

Adjust harvest limits for CMZ Q based on research studies and statistical modelling efforts.

There have been no changes between the published proposed rule and the final rule. A wide variety of public comments were submitted. It was not possible to incorporate all of the comments into the final rule as many of the comments were mutually exclusive. To view public comments, please visit www.wildlife.state.nm.us/commission/meeting-agendas/ and click on the Hearing Archive tab. The resulting rule was based on what was best for the resource and overall hunter satisfaction.

TITLE 19 NATURAL RESOURCES AND WILDLIFE
CHAPTER 31 HUNTING AND FISHING
PART 11 BEAR AND COUGAR

19.31.11.1 ISSUING AGENCY: New Mexico department of game and fish.
[19.31.11.1 NMAC - Rp, 19.31.11.1 NMAC, 4/1/2024]

19.31.11.2 SCOPE: Sportspersons interested in bear and cougar management and hunting. Additional requirements may be found in Chapter 17 NMSA 1978 and Title 19 NMAC.
[19.31.11.2 NMAC - Rp, 19.31.11.2 NMAC, 4/1/2024]

19.31.11.3 STATUTORY AUTHORITY: 17-1-14 and 17-1-26 NMSA 1978 provide that the New Mexico state game commission has the authority to establish rules and regulations that it may deem necessary to carry out the purpose of Chapter 17 NMSA 1978 and all other acts pertaining to protected mammals, birds and fish.
[19.31.11.3 NMAC - Rp, 19.31.11.3 NMAC, 4/1/2024]

19.31.11.4 DURATION: April 1, 2024 through March 31, 2028.
[19.31.11.4 NMAC - Rp, 19.31.11.4 NMAC, 4/1/2024]

19.31.11.5 EFFECTIVE DATE: April 1, 2024, unless a later date is cited at the end of a section.
[19.31.11.5 NMAC - Rp, 19.31.11.5 NMAC, 4/1/2024]

19.31.11.6 OBJECTIVE: Establishing open hunting seasons and regulations, rules and procedures governing the distribution and issuance of bear and cougar licenses and permits by the department.
[19.31.11.6 NMAC - Rp, 19.31.11.6 NMAC, 4/1/2024]

19.31.11.7 DEFINITIONS:

A. "Bear entry permit" shall mean a permit awarded through a public drawing which entitles the holder of an over-the-counter bear license to hunt in a limited entry area during season dates established in rule.

B. "Bear zones" shall mean hunt areas consisting of one or more game management units as described in 19.30.4 NMAC.

C. "Cougar zones" shall mean hunt areas consisting of one or more game management units as described in 19.30.4 NMAC.

D. "Department" shall mean the New Mexico department of game and fish.

E. "Director" shall mean the director of the New Mexico department of game and fish.

F. "Game management unit" or "GMU" shall mean those areas as described in 19.30.4 NMAC.

G. "Wildlife management areas" or "WMAs" shall mean those areas as described in 19.34.5 NMAC.

[19.31.11.7 NMAC - Rp, 19.31.11.7 NMAC, 4/1/2024]

19.31.11.8 ADJUSTMENT OF LICENSES, PERMITS AND HARVEST LIMITS:

A. The director, with verbal concurrence of the chairperson or their designee, may adjust the number of licenses, permits or harvest limits, up or down by no more than twenty percent within a bear zone or cougar zone, to address critical department management needs, significant changes in population levels or habitat availability. This adjustment may be applied within the specified zones to any or all of: the specific hunt codes; total harvest limits; or female harvest sub-limits.

B. The director, with verbal concurrence of the chairperson or their designee, may take management actions independent of seasons and restrictions, harvest limits or female sub-limits for population management, or to address critical situations including ungulate population protection, depredation, human health and safety or other wildlife management issues. The decision to take management actions pursuant to this subsection shall be reported to the commission.

[19.31.11.8 NMAC - Rp, 19.31.11.8 NMAC, 4/1/2024]

19.31.11.9 [RESERVED]

[19.31.11.9 NMAC - Repealed, 4/1/2024]

19.31.11.10 BEAR AND COUGAR ZONE CLOSURES, BAG LIMITS AND RESTRICTIONS:

A. Zone closures: Bear and cougar may be hunted or taken only in zones designated as open on the department hotline or website. Zones will close within 72 hours of when the reported number of bears or cougars harvested is within ten percent of the total limit or female sub-limit for that zone, whichever occurs first.

B. Bag limit: The bag limit for bear is one; the bag limit for cougar is two. It is unlawful to kill a bear sow with cub(s) or any bear cub less than one year old, or to kill a spotted cougar kitten or any female cougar accompanied by spotted kitten(s).

C. Limited entry hunt areas: It shall be unlawful to hunt bear or cougar in designated WMAs or other specifically designated special entry hunt areas with the following exceptions:

(1) Legally licensed bear hunters possessing a valid bear entry hunt permit may hunt bears in the area(s) specified on the permit, or as otherwise allowed by rule. Bear entry hunters shall be allowed to hunt in any other open bear zone provided they have a valid bear license.

(2) Legally licensed deer and elk hunters whose license is valid on a WMA or the Valle Vidal and are in possession of a valid over-the-counter bear or cougar license, may hunt bear or cougar in the WMA or the Valle Vidal as specified on their deer or elk license. Deer or elk hunters choosing to hunt bear or cougar under this provision may not use dogs, may hunt only in open bear or cougar zones, and must adhere to the weapon type restriction and season dates as specified by their deer or elk licenses.

D. Cougar hunting requirements and restrictions:

(1) All persons shall complete the mandatory cougar identification course offered on the department's website prior to purchasing a cougar license.

(2) Cougar hunting is closed in the Florida mountains hunt area during any open Persian ibex season, except by legally licensed Persian ibex hunters in possession of a valid cougar license. Persian ibex hunters may hunt cougar only if the cougar zone is open, and must adhere to the weapon type restrictions and season dates as specified by their Persian ibex license.

[19.31.11.10 NMAC - Rp, 19.31.11.10 NMAC, 4/1/2024]

19.31.11.11 BEAR HUNTING SEASONS:

A. Over-the-counter bear hunts for the 2024-25 through 2027-28 seasons: The following table lists bear zones, open GMUs, sporting arm restrictions, season dates, total harvest limits and female harvest sub-limits

Bear zone	open GMUs	bow only	any big game sporting arms	2024-25 total limit (female)	2025-26 total limit (female)	2026-27 total limit (female)	2027-28 total limit (female)
1	4, 5, 6, 7, 51, 52	9/1 - 24	9/25 - 11/15	168 (67)	168 (67)	168 (67)	168 (67)

[19.31.11.12 NMAC - Rp, 19.31.11.12 NMAC, 4/1/2024]

HISTORY OF 19.31.11 NMAC:

Pre-NMAC History: The material in this part was derived from that previously filed with the state records center and archives under:

Regulation No. 482, Establishing Seasons on Deer, Bear, Turkey, Elk, Antelope, Dusky Grouse, Tassel-Eared and Chickaree Squirrel, and Barbary Sheep, filed 5/31/1967;

Regulation No. 487, Establishing 1967 Seasons on Javelina and Barbary Sheep, filed 12/15/1967;

Regulation No. 489, Establishing Turkey Seasons for the Spring of 1968, filed 3/1/1968;

Regulation No. 491, Establishing Big Game Seasons for 1968 for Jicarilla Reservation, filed 3/1/1968;

Regulation No. 492, Establishing Seasons on Deer, Bear, Turkey, Elk, Antelope, Dusky Grouse, Tassel-Eared and Chickaree Squirrel, and Barbary Sheep, filed 6/6/1968;

Regulation No. 495, Establishing a Season on Bighorn Sheep, filed 10/2/1968;

Regulation No. 496, Establishing an Elk Season in the Tres Piedras Area, Elk Area P-6, filed 12/11/1968;

Regulation No. 502, Establishing Turkey Seasons for the Spring Of 1969, filed 3/5/1969;

Regulation No. 503, Establishing 1969 Deer Seasons for Bowhunting Only and Big Game Seasons for the Jicarilla Indian Reservation, filed 3/5/1969;

Regulation 504, Establishing Seasons on Deer, Bear, Turkey, Dusky Grouse, Chickaree and Tassel-Eared Squirrel, and Barbary Sheep, filed 6/4/1969;

Regulation No. 507, Establishing a Season on Bighorn Sheep, filed 8/26/1969;

Regulation No. 512, Establishing Turkey Season for the Spring Of 1970, filed 2/20/1970;

Regulation No. 513, Establishing Deer Season for Bowhunting Only in Sandia State Game Refuge, filed 2/20/1970;

Regulation No. 514, Establishing Seasons on Deer, Bear, Turkey, Elk, Antelope, Dusky Grouse, Tassel-Eared and Chickaree Squirrel, Barbary Sheep and Bighorn Sheep, filed 6/9/1970;

Regulation No 520, Establishing Turkey Seasons for the Spring of 1971, filed 3/9/1971;

Regulation No. 522, Establishing 1971 Seasons on Deer, Bear, Turkey, and Elk on the Jicarilla Apache Indian Reservation, filed 3/9/1971;

Regulation No. 523, Establishing Seasons on Deer, Turkey, Bear, Cougar, Dusky Grouse, Tassel-Eared and Chickaree Squirrel, Elk, Antelope, Barbary Sheep and Bighorn Sheep, filed 6/9/1971;

Regulation No. 531, Establishing a Season on Javelina, filed 12/17/1971;

Regulation No. 532, Establishing Turkey Seasons for the Spring of 1972, filed 3/20/1972;

Regulation No. 534, Establishing 1972 Seasons on Deer, Bear, Turkey, and Elk on the Jicarilla Apache Indian Reservation, filed 3/20/1972;

Regulation No. 536, Establishing Seasons on Deer, Turkey, Bear, Cougar, Dusky Grouse, Chickaree and Tassel-Eared Squirrel, Elk, Antelope, Barbary Sheep and Bighorn Sheep, filed 6/26/1972;

Regulation No. 542, Establishing a Season on Javelina, filed 12/1/1972;

Regulation No. 545, Establishing Turkey Seasons for the Spring Of 1973, filed 2/26/1973;

Regulation No. 546, Establishing 1973 Seasons on Deer, Bear, Turkey, and Elk on the Jicarilla Apache Indian Reservation, filed 2/26/1973;

Regulation No. 547, Establishing Seasons on Deer, Turkey, Bear, Cougar, Dusky Grouse, Chickaree and Tassel-Eared Squirrel, Elk, Antelope, Barbary Sheep and Bighorn Sheep, and Javelina, filed 5/31/1973;

Regulation No. 554, Establishing Special Turkey Seasons for the Spring of 1974, filed 3/4/1974;

Regulation No. 556, Establishing 1974 Seasons on Deer, Bear, Turkey, and Elk on the Jicarilla Apache Indian Reservation, filed 3/14/1974;

Regulation No. 558, Establishing Seasons on Deer, Turkey, Bear, Cougar, Dusky Grouse, Tassel-Eared and Chickaree Squirrel, Elk, Antelope, Barbary Sheep, Bighorn Sheep, Javelina, Oryx, and Ibex, filed 5/29/1974;

Regulation No. 565, Establishing Special Turkey Seasons for the Spring of 1975, filed 3/24/1975;

19.31.11 NMAC

October 27, 2023
State Game Commission Meeting

Stewart Liley, October 27, 2023

Rule Development Timeline

- **April, August, & October** – present at SGC meetings
- **April** – Rule opens, initial NMDGF ideas posted on the website
- **July** – Public meetings throughout the state
- **September** – Final NMDGF proposed rule posted on the website
- **October 27th** – Act on rule

Public Comment Summary

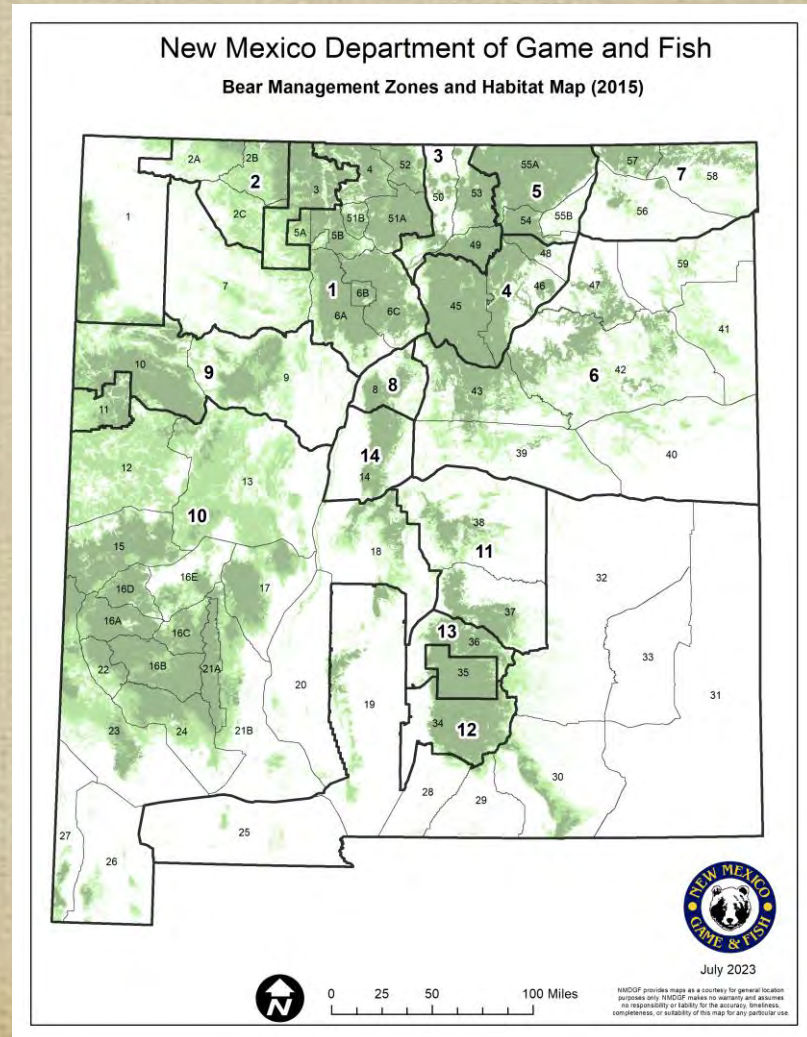

- Hosted 4 public meetings
 - Raton (11 attendees), Albuquerque (15), Las Cruces (12), Roswell (4)
- Received 2,813 emails, 10 written comments

TOPIC	
Support	1,702
Oppose	988
Alternate Proposals or Ambiguous	133

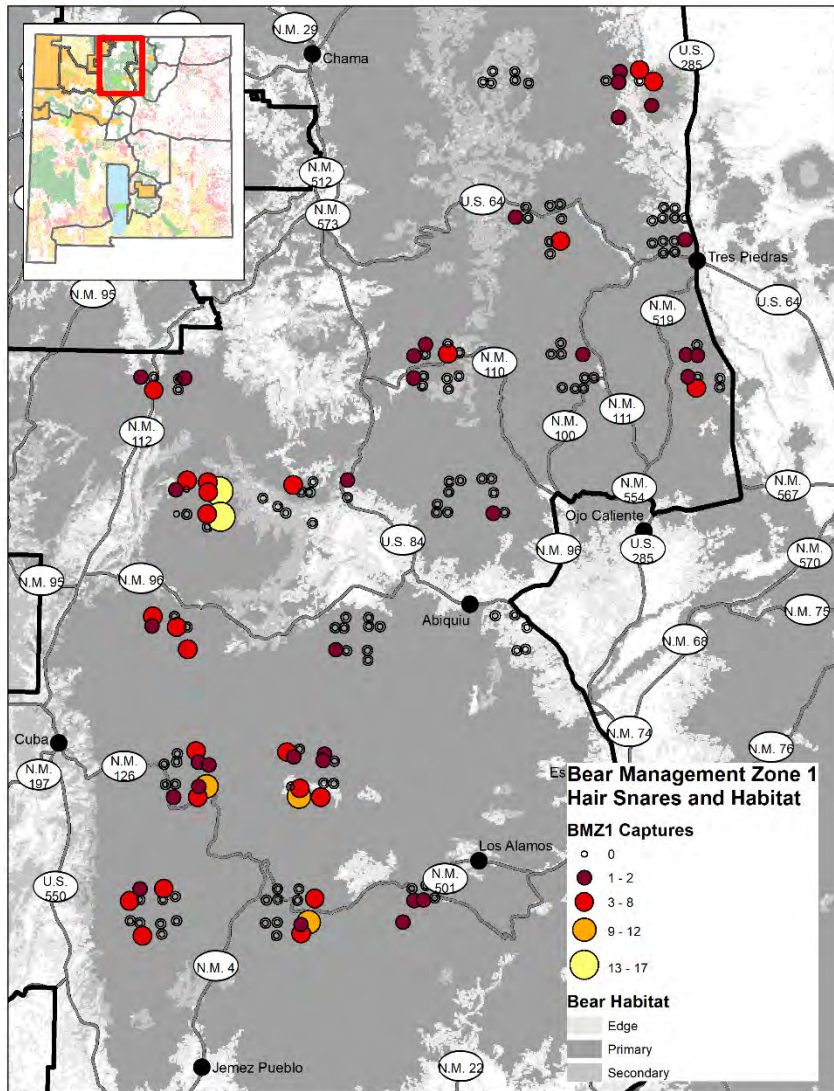

Black Bear Management Structure, Monitoring and Research

- Manage by zones
- Population estimate
- Conservative harvest limits

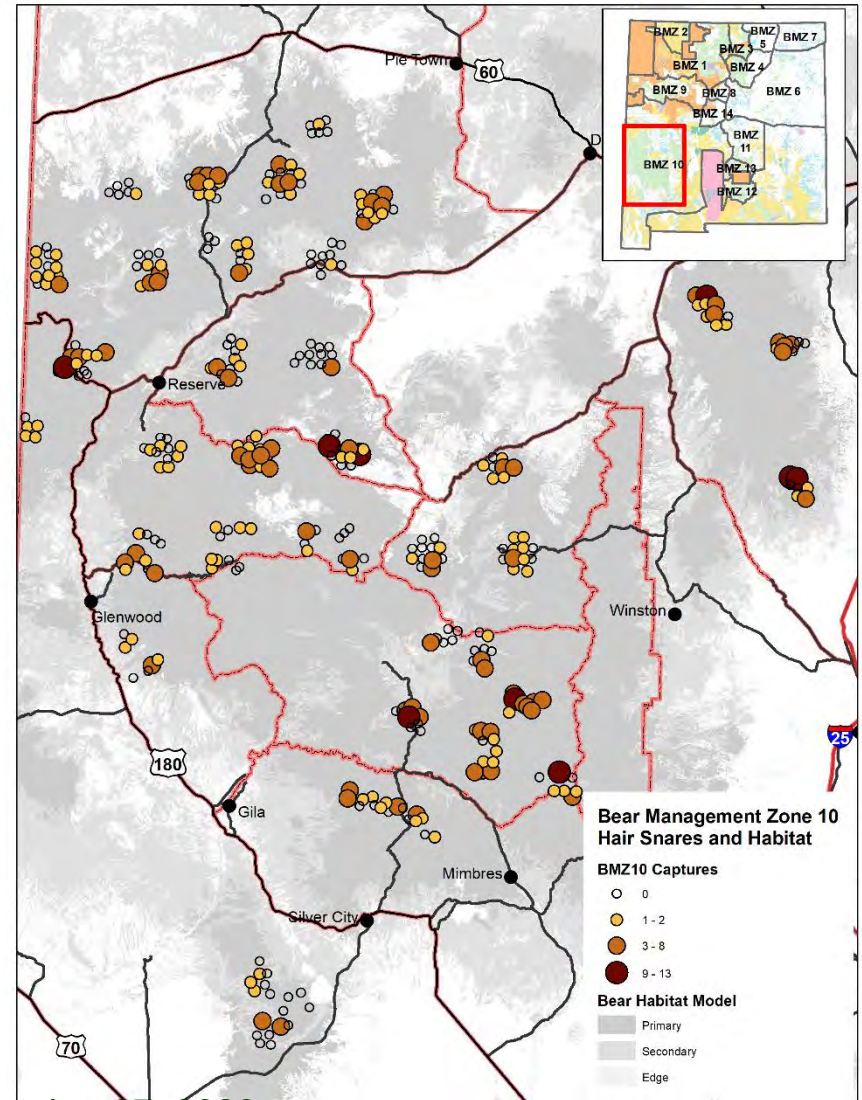

Map of Study Areas

BMZ 1 - 2019

BMZ 10 – 2020 & 2021

Stewart Liley, October 27, 2023

Bear Harvest

Year	Sport Harvest (females)	Max Allowable Harvest	Depredation	Other	Total	# of Zones Closed
2019	473 (172)	804	40	22	535	3
2020	603 (240)	804	100	41	745	6
2021	502 (192)	804	60	18	580	3

BEAR AND COUGAR RULE - PROPOSED CHANGES SUMMARY

(Updated: 8/28/2023; these proposals will be updated throughout the rule development process)

PURPOSE

Maintain sustainable bear and cougar populations and hunting opportunities throughout New Mexico using bear and cougar biology, modern monitoring and analytical methods, harvest data, and public input.

BEAR AND COUGAR BIOLOGY, MANAGEMENT, AND RESEARCH

Bear and cougar populations are distributed across the state where suitable habitat exists, and both species have been documented in nearly all of the habitat types present in the state. The disjunct mountain ranges of the state serve as clusters of preferred habitats for both species, which can drive localized population dynamics. Given these spatial dynamics, both species are managed at a Bear or Cougar Management Zone (BMZ or CMZ) level, with zones being comprised of multiple Game Management Units that encompass areas of habitat that presumably have localized population dynamics. However, both species are capable of long-distance movements, resulting in mixture and recruitment patterns at a statewide population level. Thus, population dynamics are also understood to occur at a statewide level and monitored as such.

Unregulated hunter harvest can have a negative impact on populations, therefore the Department restricts harvest so that the number of individuals harvested in a year does not exceed a harvest limit. The harvest limit is a percentage of the total population estimate for a zone. For bears the harvest limit is 8-12% of the independent-age population estimate (no harvest of cubs or females accompanied by cubs is allowed), and for cougars is 17-24% of the independent-age population estimate (no harvest of spotted-kittens, or females accompanied by spotted-kittens is allowed). In addition to the total harvest limit, the Department also restricts the number of females that can be taken by imposing a female harvest limit (40% of the total harvest limit for bears, 30% for cougars), to limit impact on the reproductive capacity of the population. Once either the total or female harvest is within 10% remaining on the limit, a zone closes to bear or cougar hunting. To ensure these harvest limits are not exceeded, it is mandatory that all hunters must present their harvested animal to a Department official.

To ensure harvest limits are set at an appropriate number, we estimate population size for each BMZ or CMZ using the best available data. Since 2012 for bears we have been using non-invasive genetic sampling techniques in combination with advanced statistical modeling to estimate zone-specific population size (for more information see: <https://www.wildlife.state.nm.us/hunting/information-by-animal/big-game/bear/>). Starting in 2017 for cougars we have been using GPS-tracking collars, trail cameras, and statistical models to estimate zone-specific population size (for more information see: <https://www.wildlife.state.nm.us/hunting/information-by-animal/big-game/cougar/>). For both species we have also recently begun building Integrated Population Models that incorporate all available data sources (survival from collared animals, age and sex data from harvested animals, hunter effort, etc.) to have annual modelling capability to keep track of these populations. By incorporating these modern techniques to generate contemporary estimates we have robust data from which to make management decisions.

PROPOSED CHANGES

General Statewide Proposed Changes

- ~~1) Change zone closure requirements such that zones close when the female harvest limit is reached, in response to updated pelt tag reporting procedures.~~
- 2) Allow licensed deer or elk hunters who draw WMA hunts to harvest a bear or cougar during their hunt if the zone is open and they possess a Bear and/or Cougar license.

Bear-specific Changes

- 1) Increase bear harvest limits based on population estimates from new NMDGF research from 2019-2021 in BMZs 1 and 10, as detailed in table below (research findings can be found at <https://www.wildlife.state.nm.us/download/hunting/species/bear/publications/Bear-NGS-and-SCR-Research-Summary-2019-2021.pdf>).

BMZ	Current 2020-2024 Total Limit (Female Sub-limit)	Proposed 2024-2028 Total Limit (Female Sub-limit)
1	158 (63)	168 (67)*
2	15 (6)	15 (6)
3	65 (26)	65 (26)
4	109 (43)	109 (43)
5	92 (37)	108 (43) ⁺
6	33 (13)	51 (20) ⁺
7	35 (14)	--- ^{+#}
8	11 (4)	11 (4)
9	36 (14)	36 (14)
10	146 (58)	197 (79)*
11	36 (14)	36 (14)
12	33 (13)	33 (13)
13	16 (6)	16 (6)
14	19 (7)	19 (7)

*Change in harvest limit reflects new research findings

+Change in harvest limit reflects GMUs being added or removed from zone

#Bear Management Zone 7 will no longer be a zone

- 2) Adjust BMZs 5, 6, and 7 such that GMU 57 will be moved from BMZ 7 into BMZ 5, and GMUs 56 and 58 will be moved from BMZ 7 into BMZ 6, thus dissolving BMZ 7 into those zones (see maps below). Harvest limit allocations from those GMUs in previous BMZ 7 will be re-allocated to the new BMZs of which they are a part (as seen in above table).

Cougar-specific Changes

- 1) Adjust harvest limits for CMZ Q based on research studies and statistical modelling efforts, as detailed in table below (research reports can be found at <https://www.wildlife.state.nm.us/download/publications/wildlife/Cougar-SMR-Research-Summary-2018-2021.pdf>).

CMZ	Current 2020-2024 Total Limit (Female Sub-limit)	Proposed 2024-2028 Total Limit (Female Sub-limit)

*Unk. - Unknown, sometimes the sex is impossible to determine due to decomposition or physical damage.

GRANT REPORTSTATE: New MexicoGRANT NUMBER: W-93-RSEGMENT NUMBER: 61GRANT TITLE: Big Game Surveys, Inventories and ManagementGRANT PERIOD: July 1, 2020 to June 30, 2021

- A. **Need:** This grant is crucial in meeting Department mission and goals and to insure compliance with state and federal mandates. Through the Commission, the Department has the responsibility, mandated by statute, to protect New Mexico's game while providing and maintaining an adequate supply for recreational use. This includes developing recommendations for hunter opportunity, engaging landowners in big game management, conducting population surveys, and restoring populations when feasible.
- B. **Purpose:** The information gathered under this grant will be used to prepare annual recommendations for big game and habitat management in accordance with the mission, goals and plans of the Commission and Department. This information may also be used by land management and other agencies and to provide the public with background biological information for their use.

Objective 5:**Conduct 15 investigations by June 30, 2021****Activity Tag 1****Fish and wildlife species data acquisition and analysis****Unit of Measure: # of investigations****Target Species : Deer, Elk, Pronghorn, Bear, Cougar, Bighorn, Oryx, Ibex****Approach**

- a. Surveys and population estimation.

Table 1. Approved population estimation/trend survey techniques, NMDGF.

Species	Approved techniques	Season	Comments
Deer	Aerial: composition	Fall, winter	Post-hunt
Deer	Ground: composition	Year-long	Post-hunt
Elk	Aerial: composition	Fall, winter, late summer (high altitudes)	None
Elk	Ground: composition	Year-long	Restricted to established roads
Pronghorn	Aerial: composition	Summer	Pre-hunt
Pronghorn	Ground: composition	Summer	Restricted to established roads

Bear	Extracted tooth; Age Est	Hunt season	Collected at Pelt tagging
Bear	Hair-snare mark-recapture	Spring/Summer	Non-invasive SECR estimates
Cougar	Mark-recapture	All seasons	Experimental w/restrictions
Cougar	Extracted tooth; Age Est	Hunt season	Collected at Pelt tagging
Bighorn	Aerial	Spring, summer, fall	
Bighorn	Ground	Spring, summer w/restrictions, fall	
Oryx	Aerial	Winter, spring	
ibex	Ground	Summer	Restricted to established roads
ibex	Aerial	All seasons	

Bear. Harvest continues to be monitored by the harvest/total sustainable mortality system. During the season, each zone remained open to black bear hunting until the total number of harvested bears (determined by mandatory check-in for successful hunters) or the female portion of the harvest equals the total limit or the female sub-limit, respectively, whichever comes first. Only a maximum of 40% of the harvest can be female in any bear management zone. Total bear mortality from all human causes this grant segment is similar to recent years (Appendix 5). For 2014-2020, reasonably low numbers of non-sport harvest bear mortalities occurred as a consequence of moderate to good availability of natural foods, resulting in decreased bear movement and decreased human contact, and a shift in Department policy regarding depredation bears.

Cougar. Harvest continues to be managed by the hunter harvest/total sustainable mortality system. During the hunting season, each zone remained open to mountain lion hunting from April 1 until March 31 or until the total number of harvested cougars (as determined by mandatory check-in for successful hunters) or the female portion of the harvest equals the total limit or the female sub-limit, respectively, whichever comes first. Only 30% of the harvest may be female in cougar management zones to manage for stable cougar populations. Harvest was similar to last year (Appendix 6), and relatively stable over the past five years with the exception of higher harvest in 2018-19 likely as a result excellent snow conditions.

- a. Cougar density estimation: Includes planning, implementing and assessment of a statewide cougar density estimation study Please see Appendix IV for the detailed Gila Project Proposal. In addition, outreach to private landowners in Cougar Management Zone P in the northeast corner of New Mexico will occur with the intent of implementing the cougar density estimation study on their private property in the future. As part of working with the landowners, up to 5 cougars may be captured and radiocollared by the Department Predator Specialist.

Cougars may be captured using traps, snares, or running hounds. The data collected from the radiocollars will help us understand home range sizes, movement patterns, and preferred habitat characteristics.

RESULTS:

Preliminary analysis was conducted on the data collected from 2018 in Cougar Management Zone B, and the findings were consistent with findings from data collected in 2017. Further refinement of the model to incorporate all data collected, model selection and a final report are still in preparation.

In November 2018, the scope of this project was extended to CMZ Q, a survey area of approximately 17,800 km², for a multi-year effort in that area. This grant period was the final year of capture for this iteration of the project, with an additional seven cougars captured and fitted with GPS collars (3 females; 3 males), or ear-tagged (1 male) in addition to the cougars captured and collared or marked in previous years. The 157 camera sites that were established in the previous years were maintained and cameras were monitored to replenish batteries, memory cards, and scent lure as needed. In April 2021, the scope of this project was extended to CMZs J and K, a survey area of approximately 33,000 km². Five cougars were captured and fitted with GPS collars (2 females; 3 males).

- b. Bear population density estimate in Bear Management Zone 10. Please see Appendix VI for the detailed Project Proposal.

RESULTS:

Hair snare sites were set up in the northern half of the Greater Gila region Bear Management Zone 10, and samples were collected throughout the summer of 2020 at the 203 established sites. Remote cameras were deployed at 41 of the sites to monitor visitation patterns and sample collection efficiency. We collected 1,013 hair samples, which are currently being analyzed to assign individual identities, for future analyses in a spatial capture-recapture framework.

In May 2021, we initiated similar efforts in the remaining areas of the Gila region of Bear Management Zone 10, and established 107 hair snare sites, of which approximately 22 were monitored by remote cameras. Sample collection began in the second week of June, and samples will be analyzed to assign individual identities to provide data for a spatial capture-recapture estimation of population density in this zone.

GRANT STATEMENT

STATE: New Mexico

GRANT NUMBER: W-93-R62

GRANT TITLE: Big Game Surveys, Inventories and Management

GRANT PERIOD: July 1, 2021 to June 30, 2022

- A. **Need:** This grant is crucial in meeting Department mission and goals and to insure compliance with state and federal mandates. Through the Commission, the Department has the responsibility, mandated by statute, to protect New Mexico's game while providing and maintaining an adequate supply for recreational use. This includes developing recommendations for hunter opportunity, engaging landowners in big game management, conducting population surveys, and restoring populations when feasible.
- B. **Purpose:** The information gathered under this grant will be used to prepare annual recommendations for big game and habitat management in accordance with the mission, goals and plans of the Commission and Department. This information may also be used by land management and other agencies and to provide the public with background biological information for their use.

Objective 5:

Research, survey, data collection
and analysis

Conduct 15 investigations by June
30, 2022 Activity Tag 1

Fish and wildlife species data acquisition
and analysis Unit of Measure: # of
investigations

Species: elk (*Cervus canadensis*), deer (*Odocoileus hemionus*, *Odocoileus virginianus*), pronghorn (*Antilocapra americana*), bighorn sheep (*Ovis canadensis*), bear (*Ursus americanus*), cougar (*Puma concolor*), oryx (*Oryx gazella*), ibex (*Capra aegagrus*), barbary sheep (*Ammotragus lervia*)

Approach

- a. Surveys and population estimation.

Table 1. Approved population estimation/trend survey techniques, NMDGF.

Species	Approved techniques	Season	Comments
Deer	Aerial: composition	Fall, winter	Post-hunt
Deer	Ground: composition	Year-long	Post-hunt
Elk	Aerial: composition	Fall, winter, summer (high altitudes)	None
Elk	Ground: composition	Year-long	Restricted to established roads
Pronghorn	Aerial: composition	Summer	Pre-hunt
Pronghorn	Ground: composition	Summer	Restricted to established roads

Bear	Extracted tooth; Age Est	Hunt season	Collected at Pelt tagging
Bear	Hair-snare mark-recapture	Spring/Summer	Non-invasive SECR estimates
Cougar	Mark-recapture	All seasons	Experimental w/restrictions
Cougar	Extracted tooth; Age Est	Hunt season	Collected at Pelt tagging
Bighorn	Aerial	Spring, summer, fall	
Bighorn	Ground	Spring, summer w/restrictions, fall	Vehicle travel restricted to established roads
Oryx	Aerial	Winter, spring	
Oryx	Ground	Summer	Vehicle travel restricted to established roads
Ibex	Ground	Summer	Vehicle travel restricted to established roads
Ibex	Aerial	All seasons	
Barbary	Ground: composition	All seasons	Vehicle travel restricted to established roads
Barbary	Aerial	All seasons	

Bear. Harvest continues to be monitored by the harvest/total sustainable mortality system. During the season, each zone remains open to black bear hunting until the total number of harvested bears (determined by mandatory check-in for successful hunters) or the female portion of the harvest equals the total limit or the female sub-limit, whichever comes first. Only a maximum of 40% of the harvest can be female in any bear management zone. Total bear mortality from all human causes during this grant segment is similar to recent years, with the exception of the higher hunter harvest and depredation during 2020-21 that were likely due COVID-19 related increases in participation in outdoor activities and observations of bears while people were at home (Appendix 10).

Cougar. Harvest continues to be managed by the hunter harvest/total sustainable mortality system. During the hunting season, each zone remained open to mountain lion hunting from April 1 until March 31 or when the total number of harvested cougars (as determined by mandatory check-in for successful hunters) equaled the total sustainable mortality limit for that zone, or the female sub-limit had been met, whichever came first. Harvest was similar to last year (Appendix 11), and relatively stable over the past five years with the exception of higher harvest in 2018-19 that was likely a result of excellent snow conditions that year.

Big Game Survey Data

- a. Cougar density estimation: Includes planning, implementing and assessment of a cougar density estimation study in the Gila. The New Mexico Department of Game and Fish proposes to conduct capture and collaring of up to 40 cougars that will be 're-captured' via photographs from remote cameras. Department staff will capture cougars through live trapping and pursuit with dogs, and deploy remote cameras in a clustered-grid design. Cameras will be deployed for up to six months, and checked every two months.

RESULTS:

Cougar density estimation: Includes planning, implementing and assessment of a statewide cougar density estimation study. By March 2022, we retrieved all camera traps that were deployed in CMZ Q for that iteration of this survey. All photographs were downloaded, and photo identification was started for the 3-year data set.

In early 2021, the scope of this project was extended to portions of CMZs G, J and K, a survey area of approximately 23,000 km². During the grant period 36 cougars were captured and either fitted with GPS collars (14 females, 19 males) or ear-tagged (2 females, 1 males) if they were not large enough for a collar. During the spring of 2022 we established 81 camera sites (162 total cameras) in clusters across the main collaring area in GMUs 15, 16A, and 16D, which were operational through the end of the grant period.

- b. Bear population density estimate in Bear Management Zone 10. Hair will be collected via 'hair snare' devices consisting of a barbed wire corral with bait in the center of the corral. As the bear passes over or under the barbed wire, the barbs will pull hair which will be collected once a week. Sites will be checked for up to 10 weeks during the summer. At the end of field sampling, hairs will be sent to a genetics lab for analysis to build capture profiles for each individual that visited the hair snares.

RESULTS

The goal of this study is to provide black bear demographic and ecological information to inform black bear management in New Mexico using non-invasive collection of hair samples for genetic analysis. We monitored 107 hair snare sites from July to August 2021, and collected 694 hair samples. Hair samples are being analyzed to assign individual identities for future analyses in a spatial capture-recapture framework.

Results from the genetic analysis of the 2020 sampling in the Gila region were received in December of 2021. Of the 1,013 samples collected, 725 were able to be genotyped and assigned to an individual (71.5% overall genotyping success). Those 725 samples that were successfully genotyped were assigned to 152 individuals (74F:78M). Tissue samples collected from hunter harvested bears in 2020 from BMZ 1 (n=78, where the study was conducted in 2019) and BMZ 10 (n=92) were analyzed. Of those tissue samples, four individuals from the BMZ 1 harvest matched to individuals identified from hair snares in 2019, and 9 individuals from the BMZ 10 harvest matched to individuals identified from hair snares in 2020.

In June 2022, we initiated similar efforts in Bear Management Zones 5 and 7, and established 197 hair snare sites, of which 124 were monitored by remote cameras. Sample collection began late June.

SCIENTIFIC REPORTS

OPEN

Improving estimation of puma (*Puma concolor*) population density: clustered camera-trapping, telemetry data, and generalized spatial mark-resight models

Sean M. Murphy^{1,5}, David T. Wilckens¹, Ben C. Augustine², Mark A. Peyton³ & Glenn C. Harper⁴

Obtaining reliable population density estimates for pumas (*Puma concolor*) and other cryptic, wide-ranging large carnivores is challenging. Recent advancements in spatially explicit capture-recapture models have facilitated development of novel survey approaches, such as clustered sampling designs, which can provide reliable density estimation for expansive areas with reduced effort. We applied clustered sampling to camera-traps to detect marked (collared) and unmarked pumas, and used generalized spatial mark-resight (SMR) models to estimate puma population density across 15,314 km² in the southwestern USA. Generalized SMR models outperformed conventional SMR models. Integrating telemetry data from collars on marked pumas with detection data from camera-traps substantially improved density estimates by informing cryptic activity (home range) center transiency and improving estimation of the SMR home range parameter. Modeling sex of unmarked pumas as a partially identifying categorical covariate further improved estimates. Our density estimates (0.84–1.65 puma/100 km²) were generally more precise (CV = 0.24–0.31) than spatially explicit estimates produced from other puma sampling methods, including biopsy darting, scat detection dogs, and regular camera-trapping. This study provides an illustrative example of the effectiveness and flexibility of our combined sampling and analytical approach for reliably estimating density of pumas and other wildlife across geographically expansive areas.

Pumas (cougars or mountain lions; *Puma concolor*) are the most widely distributed large carnivore in the western hemisphere¹. Similar to other large carnivores, pumas have considerable resource requirements and provide important ecological benefits over expansive areas^{1–3}. Their presence sometimes results in conflicts with humans, however, and predation by pumas can influence vital rates of terrestrial ungulate populations^{4,5}. Although some puma populations have recently expanded range and present novel management challenges^{6,7}, other populations are small, isolated, or otherwise imperiled and might necessitate conservation intervention^{8,9}. Conservation and management of pumas are often contentious issues that are influenced by multiple political, social, and economic interest groups, and resolving disputes has increasingly hinged on managing authorities possessing reliable and contemporary estimates of puma population density and abundance^{10–12}. However, pumas are wide-ranging, cryptic, and notoriously difficult to detect; consequently, few jurisdictions within the species' occupied range have reliable estimates of those demographic parameters. Most puma populations are instead managed based on population indices, such as hunter effort, mortality trends, or expert opinion, extrapolation of densities from

small study areas and other jurisdictions, or a combination thereof^{10,13–15}, all of which may be unreliable and could result in flawed conservation and management^{16,17}.

Spatially explicit capture-recapture models integrate a detection process model with an ecological process model that describes the spatial distribution of animal activity centers, or home range centers, across a study area, and can produce unbiased estimates of population density^{18,19}. Recent studies have applied spatially explicit models to multiple types of detection data to estimate puma population density; for example, tissue samples collected by biopsy darting pumas that were treed using hounds^{20–22}, puma scat collected via area searches by scat detection dogs²³, and photographs of pumas collected from regular or contiguous arrays of remote camera-traps^{24–27}. However, biopsy darting and scat detection dog sampling necessitate often expensive laboratory genetic analyses to produce individual identities from detection data²⁸. Additionally, treeing pumas with hounds for biopsy darting is likely most efficient during winter and in locales with sufficient snow cover that improves tracking^{20,22}, and because of high DNA degradation rates in scat that can reduce sample sizes, optimal effectiveness of scat detection dog sampling is generally limited to locales with cool and dry climates^{29,30}. In contrast, remote camera-trapping can be a cost-efficient and logistically feasible approach for effectively detecting pumas and other large carnivores across habitats, ecosystems, and climatic conditions^{31,32}.

A critical assumption of most capture-recapture models is that all detected animals are individually identifiable¹⁹. This can be difficult to achieve if camera-traps are used to detect pumas or other wildlife that lack visible, individually unique natural markings, such as the rosettes on jaguars (*Panthera onca*)^{24,33}. To overcome this issue, mark-resight models and their spatially explicit analogues, spatial mark-resight (SMR) models, were developed to estimate the density of populations in which only a portion of animals are individually identifiable^{26,34–37}. Attempting to assign individual identities to pumas *ad hoc* based on perceived natural marks, such as scars, ear nicks, body shapes, or carriages^{25,27}, can result in biased and unreliable density estimates, however, because multiple individuals may have similar physical features, causing observers to agree on incorrect identity assignments or disagree on correct identity assignments²⁴. Furthermore, given the ambiguity, it is not always possible to identify a sufficient number of individually unique pumas based solely on natural marks to estimate population density^{24,38}.

For pumas and other species that lack unambiguous natural markings, physically capturing and applying artificial marks, such as radiocollars or ear tags, to a portion of animals in a population is likely necessary for accurate density estimation when using camera-traps for detection^{26,32,34–37}. Such mark-resight methods can be viable, cost-effective alternatives to capture-recapture methods, because only a single marking event of a portion of a population is required and camera-trapping to collect resighting data is efficient. Using Global Positioning Systems (GPS) collars as marks can permit unambiguous individual identification for nearly all camera-trap detections of marked individuals, assist with determining whether an animal is marked or unmarked, and also provide telemetry location data that can be integrated in spatially explicit models to improve estimation of individual activity centers, the detection function spatial scale (home range) parameter (σ), and ultimately, population density^{26,36,37,39}.

One challenge associated with using researcher-applied artificial marks is that in SMR models, the spatial distributions of marked and unmarked individuals across the landscape are informed by the capture and marking process; therefore, correctly specifying those distributions in the process model is critical for accurately estimating population density^{35,37}. Conventional spatial mark-resight (conSMR) models assume that marked and unmarked individuals have the same spatial distribution, typically uniformity or that the two distributions can be specified correctly with parametric distributions^{26,34,36}. Although the assumption of spatial uniformity may be valid for jaguars and other species that are identifiable by their individually unique natural markings, it is likely inappropriate if animals are physically captured and artificially marked, because of the juxtaposition between marking and resighting locations^{35,37}. If the marking and resighting detector arrays overlap, animals that are captured for marking are located on average closer to the resighting array than unmarked individuals and, therefore, likely will have higher detection rates than unmarked individuals. Consequently, if researcher-applied artificial marks are used for individual identification, conSMR models, which do not account for the capture and marking process, may underestimate the numbers of both unmarked and undetected individuals and thus, population density^{35,37}.

A generalized spatial mark-resight model (genSMR) was recently developed that resolves this problem by including sub-models for both the marking and resighting processes³⁷. This allows the differing spatial distributions of marked and unmarked individuals to be determined by the marking process, and simulations have demonstrated that the genSMR model produces unbiased estimates of population density when marking is not random across a study area³⁷. The parameters of the genSMR model developed by Whittington *et al.*³⁷ are estimated via Bayesian methods using Markov chain Monte Carlo (MCMC) algorithms. In contrast, Efford and Hunter³⁵ developed a pseudolikelihood-based model and estimation procedure that is analogous to genSMR, which they refer to as spatial capture-mark-resight. A primary limitation of this pseudolikelihood estimation procedure is that it ignores information contained in the spatial distribution of detections of unmarked individuals. Efford and Hunter³⁵ argued that the information lost by discarding these data is minimal; however, the magnitude of information in the spatial locations of detections of unmarked animals can be increased through the use of partial identity covariates^{34,39}.

A key source of uncertainty in SMR models stems from the need to probabilistically resolve the individual identities for detections of unmarked animals, as well as detections of marked but unidentifiable animals and animals with unknown mark status, if available^{34,39}. Reducing uncertainty in the individual identity assignments can reduce the uncertainty in population density estimates, which can be accomplished with partial identity covariates^{39,40}. The use of categorical partial identity covariates in the form of microsatellite loci genotypes has been demonstrated^{39,40}, but the utility of partially identifying information in camera-trap studies, where animal sex and other potential covariates are fewer in number and less reliably determined from photographs, has not been explored. Such covariates are typically either not recorded or are discarded from camera-trap detection data, so evaluating their effectiveness for improving the precision of parameter estimates from spatially explicit models could result in improved density estimation in camera-trapping studies.

Because of the logistical and financial constraints associated with currently available puma sampling methods and survey designs, researchers are often forced to estimate puma population density for areas that are smaller than the geographical extent of populations or the scale at which conservation and management occur^{10,15}. Population density estimates are then extrapolated to larger areas, typically with considerable uncertainty and unverified assumptions^{10,13–15}. By incorporating spatial information about when and where individual animals are detected, spatially explicit models are robust to irregular sampling designs, such as clusters of detectors with gaps between clusters, which can permit efficient surveying of large geographical areas^{18,41–45}. Recent studies evaluated clustered sampling designs of noninvasive genetic hair-traps in the spatially explicit framework for estimating American black bear (*Ursus americanus*) population density, which demonstrated that density estimates were improved, largely because more individuals were exposed to detectors and spatial recaptures were obtained over expansive areas^{41,43–45}. Remote camera-trapping is arguably the most widely used and practical noninvasive method for surveying wildlife populations globally^{31,32}; therefore, considerable potential exists for using clustered sampling designs in camera-trap studies to estimate population density over spatially extensive areas, which could have widespread practical utility across terrestrial wildlife species and geographical locales.

Herein, we apply clustered sampling to camera-traps in the spatially explicit framework to demonstrate the potential for this approach to survey pumas over expansive areas with reduced effort. We then apply recently developed genSMR models to the obtained camera-trap detection data to estimate puma population density and abundance. In addition, we evaluate the influence on parameter estimates of integrating telemetry data from GPS collars on marked pumas, incorporating sex as a categorical identity covariate for unmarked pumas, and accommodating activity center transiency. Our results demonstrate the flexibility of genSMR models and provide an illustrative example of the effectiveness of this combined sampling and analytical approach to produce precise and reliable population density estimates over large geographical areas.

Materials and Methods

Study area. Our study occurred during 2017 in the Southern Rocky Mountains ecoregion in north-central New Mexico, USA (Fig. 1). The area was rugged, with steep mountains, deep canyons, and expansive mesas, and elevations ranging from 1,540 to 3,524 m a.s.l. The climate was semi-arid, with average annual rainfall ranging from 22.58 to 57.63 cm and average annual snowfall ranging from 18.03 to 305.31 cm, depending on elevation; average annual high temperatures ranged from 13.72 to 22.05 °C and average annual low temperatures ranged from −4.17 to 3.00 °C, depending on elevation⁴⁶. The majority of lands (63%) were under federal management by the U.S. Forest Service, National Park Service, or Bureau of Land Management; tribal lands (29%) and a combination of state government, local government, and privately owned lands (8%) accounted for the remainder of land area.

Live-capture and marking. To apply artificial marks to a portion of individuals, we live-captured pumas throughout our study area using Aldrich spring-activated foothold cable restraints, foothold traps, and to a lesser extent, treeing with a team of trained hounds^{47,48}. We chemically immobilized captured pumas using one of the following drug combinations⁴⁹: (1) tiletamine and zolazepam (Telazol®; Zoetis Services LLC, Parsippany, USA) at a dosage of 5.0 mg/kg combined with 1.0 mg/kg of xylazine (AnaSed®, LLOYD Inc., Shenandoah, USA), the latter of which was antagonized using 0.12 mg/kg of yohimbine (ZooPharm, Windsor, USA); or (2) 2.0 mg/kg of ketamine combined with 0.07 mg/kg of medetomidine, the latter of which was antagonized using 0.30 mg/kg of atipamezole (ZooPharm). During immobilization, we monitored the respiratory rate, heart rate, and body temperature of each puma at five-minute intervals to ensure maintenance of bodily function. We outfitted captured pumas that were field-aged based on gum recession measurements⁵⁰ as being ≥ two years-old (i.e., subadults and adults)⁴⁸ with a uniquely numbered ear tag and an Iridium GPS collar (Advanced Telemetry Systems [Isanti, USA] or Vectronic Aerospace [Berlin, Germany]). We programmed collars to acquire location fixes every one to three hours (i.e., 8–24 fixes per calendar day) and we remotely downloaded location data every three to seven days. All pumas were released at the location where captured.

Clustered camera-trap resighting. We created a survey design comprised of nine total clusters of 3 × 3 sampling cells in each cluster (Fig. 1). Cell spacing within a cluster was 3.5 × 3.5 km, or 12.25-km² coverage per cell and 110.25-km² coverage per cluster; this spacing corresponded to the recommended ≥ two detectors within the smallest female home range size^{43,45} reported for pumas in New Mexico (30.10 km²)⁵¹. Clusters were staggered with 28-km longitudinal spacing and 36–45-km latitudinal spacing between the centers of clusters, or 4.5–7 × the diameter of said smallest female home range size, assuming a bivariate normal distribution (i.e., circular home range)¹⁹. Prior to deploying camera-traps, we used simulation to evaluate the performance of this clustered survey design for estimating population density, given pessimistic parameter estimates and various numbers of sampling occasions^{19,41,45}. For a simulated hypothetical population with low density (1.0 puma/100 km²), low baseline detection rate ($\lambda_0 = 0.05$), and large spatial scale of the detection function ($\sigma = 5.0$ km)^{20,25}, results from a fitted null spatial capture-recapture model indicated that surveying this design for 17 consecutive occasions would likely estimate population density with high precision and accuracy (CV = 0.18; RMSE = 0.19), negligible bias (+0.05, 95% CI = 0.00–0.09), and nominal coverage (0.97, 95% CI = 0.94–1.00; see Supplementary Table S1). These simulations assumed that all individuals had unambiguous identities, which deviates from the mark-resight framework, but the effectiveness of survey designs for spatial capture-recapture and SMR models are similar¹⁹.

We attempted to establish a single camera-trap within each sampling cell along canyon rims, ridges, saddles, drainages, trails, and other terrain features that could be likely travel routes for pumas; we did not place camera-traps on roads. Because of restricted property access, we were unable to establish camera-traps in some cells; thus, our final array was comprised of 68 total camera-traps (range: 3–9 camera-traps/cluster). Each camera-trap consisted of two cameras with passive infrared motion-activated sensors (Reconyx® HyperFire PC800; Holmen, USA), which we placed four to six m apart, facing each other, and mounted to trees

Figure 1. Study area in New Mexico, USA, where pumas were live-captured and marked with GPS collars, and camera-traps were deployed in a systematic cluster design for resighting of marked and unmarked pumas to estimate population density with generalized spatial mark-resight models. The spatial locations of live-traps (orange circles), camera-trap sampling cells (solid black outline squares), thinned telemetry locations collected during the resighting period (triangles with discrete colors corresponding to individual), and parameter estimation area (state space; dashed black line) are presented. Image created by S.M.M. with ESRI® ArcMap™ 10.4.1 software (<http://desktop.arcgis.com/en/>) under license (<https://technology.ky.gov/gis/Pages/PostSecondarySiteLicense.aspx>), with forest-shrub land cover data (green shaded areas) from the U.S. Government (<https://www.mrlc.gov/data/nlcd-2011-land-cover-conus>)⁷⁹; topography data (background) from ESRI, U.S. Geological Survey, and National Oceanic and Atmospheric Administration (https://server.arcgisonline.com/ArcGIS/rest/services/World_Terrain_Base/MapServer); and major highways data (red lines) from New Mexico Department of Transportation (http://services.arcgis.com/hOpd7wfnKm16p9D9/arcgis/rest/services/NMDOT_Functional_Class/FeatureServer).

or shrubs ~one m above the ground⁵². We set cameras to medium sensitivity with bursts of five photos per detection and 30-s delays between bursts. We placed ~1.0 mL of bobcat (*Lynx rufus*) gland-based or rub-eliciting scent lure on the ground in the center of each camera-trap. These lures provided no caloric reward, and felids do not have the extraordinary olfactory capabilities that canids and ursids do⁵³; neither pumas, jaguars, nor leopards (*Panthera pardus*) have exhibited a behavioral response (i.e., trap-happy or trap-shy) to detection when bobcat lure was applied^{54–56}. If a camera-trap is visited, however, bobcat lure can entice pumas to linger for a slightly extended period of time, thereby affording researchers the opportunity to identify the sex and marked status of an individual from photographs^{24,57,58}.

We operated camera-traps for 17 consecutive seven-day occasions from July to November 2017, and we visited each camera-trap every 21–28 days to retrieve photographs, check battery levels, and reapply lure. We considered individual photographs of pumas that were acquired \geq one hr apart as unique detections^{24,25}. We excluded dependent kittens, which are not reproductively mature, from the detection history to prevent inflation of density estimates^{13,20}; therefore, our results represent subadult and adult pumas only. We first classified photographs by the mark status of each puma based on the presence or absence of a GPS-collar: (1) marked and identifiable, (2) marked but unidentifiable, (3) unmarked, or (4) unknown. We then identified marked pumas to the individual level based on a combination of ear tag, collar type, sex, and telemetry locations from GPS collars^{26,37}. We did not attempt to assign individual identities to any non-collared pumas based on perceived natural marks, because of the inherent uncertainty that could bias density estimates²⁴. We reclassified all pumas that we initially assigned unknown mark status as unmarked if photograph date and time did not align with telemetry location data for GPS-collared individuals. Similarly, we resolved all cases of marked but unidentifiable individuals by comparing telemetry locations with photograph date and time. We identified the sex of unmarked pumas when possible; for photographs from which puma sex was inconclusive, we assigned individuals unknown sex.

Spatial mark-resight analysis. We estimated puma population density using the live-capture history (marking), the camera-trap detection history (resighting), and the telemetry locations from GPS-collared pumas. Because only two pumas were captured and marked via treeing with hounds, we did not explicitly model a separate hound capture process; however, we retained hound-captured pumas in our data as marked individuals that were exposed to both the marking and resighting processes, and they also provided telemetry data that informed their activity center locations and contributed to estimation of the detection function spatial scale parameter. To jointly use all of those sources of information and account for dependency among data types, we used a Bayesian genSMR model³⁷ that specified a spatial capture-recapture density and activity center process model that was observed in three ways: (1) through the marking process in which all individual identities were known; (2) through the resighting process in which only the individual identities of marked pumas were known and unmarked identities could be partially known if sex was observed; and (3) through the telemetry process for the marked individuals with known identity. To reduce the uncertainty in probabilistically resolving the latent identities of unmarked individuals³⁴, we used sex as a categorical identity covariate to exclude particular combinations of detections^{39,40}; for example, an unmarked male detection could not be from the same individual as an unmarked female detection. This assumed that the sex of individual i , $sex_i \sim \text{Bernoulli}(p^{sex})$, where p^{sex} is the probability that an individual is female, which must be estimated. Using this assumption, sex can be probabilistically resolved for detections of individuals whose sex was not identified from photographs²², and the individual identities of unmarked pumas can be probabilistically resolved using the algorithms developed by Chandler and Royle³⁴, excluding identity matches between detections of different sexes. We also fit conSMR models, which ignore the marking process^{26,34,36}, to permit comparisons with genSMR models. We accommodated all of the aforementioned features using MCMC algorithms that are maintained in the R statistical software package SPIM^{59,60}.

We considered the following two process models for activity centers (s). First, we used a typical spatial capture-recapture point process model in which individual i had a single s_i for the entirety of the study (marking and resighting combined), and all s_i were uniformly distributed across space ($s_i \sim \text{Uniform}(\mathbf{S})$ for $i = 1, \dots, N$, where \mathbf{S} denotes the two-dimensional state space [parameter estimation area])¹⁹. To define the state space for genSMR models, we buffered the minimum and maximum longitude and latitude extents of the combined live-trap and camera-trap locations by 25 km, or $\sim 3 \times$ the maximum estimated spatial scale of the detection function parameter that was pooled between marking and resighting processes (σ^d)¹⁹, resulting in $S^G = 15,314 \text{ km}^2$. In contrast, because conSMR models do not incorporate the marking process, the 25-km buffer was applied only to the camera-trap locations to define a state space for conSMR models of $S^C = 14,707 \text{ km}^2$. Second, GPS-collar telemetry data indicated that the activity centers for four marked pumas may have spatially shifted large distances between the marking and resighting processes, and one marked puma died prior to the onset of resighting (see Results). Therefore, we also specified a spatial point process model for activity center transiency, which estimated the locations of individuals' activity centers separately for each the marking and resighting processes^{61,62}. This process model accommodated activity center relocations between marking and resighting, including if individuals relocated to fill the territorial vacancy that resulted from the death of one marked puma^{63,64}. An individual's activity centers were connected by a spatially constrained relocation event (described in detail below), which entailed that resighting activity centers must be spatially linked to the location where each marked puma was live-captured, thereby constituting an activity center model that was intermediate between conSMR and genSMR models^{61,62}.

We defined data for the marking and resighting processes using the M and R superscripts, respectively. The previously mentioned two-step process model for genSMR models required us to specify two sets of activity centers, s_i^M and s_i^R , for $i = 1, \dots, N$. We assumed spatial uniformity of activity centers for the marking process, $s_i^M \sim \text{Uniform}(S^G)$. For the resighting process, we assumed $s_i^R \sim \text{Bivariate Normal}(s_i^M, \Sigma)[(x_{\min}, y_{\min}), (x_{\max}, y_{\max})]$, where $\Sigma = \sigma^t \mathbf{I}$, and σ^t is the spatial scale parameter for activity center transiency; the bivariate normal redistribution kernel was truncated by the extent of S^G to prevent σ^t underestimation⁶². This model for redistribution (i.e., spatial shift) has been used in both open and closed population spatial capture-recapture models^{62,65}, the latter of which allowed fully transient activity centers and was recently applied to conSMR models⁶¹. In contrast to those implementations, we only allowed one spatial redistribution of activity centers, because that was all that was necessary to accommodate the spatial dynamics that we observed, and fewer activity center shifts should maintain greater precision and better MCMC mixing, which is typically poor for spatially explicit models that accommodate transient activity centers^{61,62}.

Conditional on the aforementioned process models, the population was observed via three processes. For the marking and resighting processes, observations were made at the $J^M \times 2$ live-trap locations X^M and the $J^R \times 2$ camera-trap locations X^R , where J^M and J^R are the number of live-trap and camera-trap locations, respectively. We assumed a hazard half-normal detection function with binomial detections for the marking process, producing individual by live-trap detections summed across occasions, $Y_{ij}^M \sim \text{Binomial}(p_{ij}^M, K^M)$, where K^M is the number of marking occasions. For the resighting process, we assumed a Poisson detection function, producing individual by camera-trap counts that were summed across occasions; specifically, $Y_{ij}^R \sim \text{Poisson}(K^R \times p_{ij}^R)$, where K^R is the number of resighting occasions. These observation models had σ^d and baseline detection rate parameters that varied by process (λ_0^M and λ_0^R). Telemetry locations from GPS collars could be recorded anywhere within the extent of \mathbf{S} . We used only the telemetry locations that were collected during the resighting period, which we thinned to one randomly selected location per survey occasion for each marked puma (i.e., one location/week). We applied this thinning to decrease temporal dependence among telemetry locations for each puma, because temporal dependence could cause underestimation of the variance of σ^d and σ^t , activity centers, and population density^{26,36,37}. Telemetry locations informed the estimation of σ^d and s_i , or σ^d , s_i^M , and σ^t for models that included activity center transiency.

We accounted for unequal live-trap and camera-trap operation (effort) across time, and also a puma that died prior to initiation of resighting, using individual by trap exposure matrices. These matrices are similar to a trap

operation file¹⁹, except that the exposure of each puma to each trap and trap type could differ; this allowed for known entries and exits into and out of the population, but did not account for unknown violations of the population closure assumption^{37,39}. For the marking process, the $A \times J^M$ exposure matrix E^M contained the number of occasions that individual i was exposed to detection at a live-trap j , where A indicates the level of data augmentation⁶⁶. For the resighting process, the $A \times J^R$ exposure matrix E^R contained the number of occasions that individual i was exposed to detection at camera-trap j . These exposure matrices were substituted into the binomial and Poisson observation models for K^M and K^R , respectively. To correctly allocate latent identity samples for two pumas that were live-captured and marked during the resighting period and one marked puma that died prior to resighting, we used an $n^M \times K^M$ matrix m , where n^M is the number of marked pumas, to denote the marked status of each GPS-collared puma during each resighting occasion (0 = unmarked, 1 = marked, and 2 = dead)³⁷. Thus, if a puma was unmarked on occasion k , it could be allocated latent identity unmarked detections. If a puma was marked on occasion k , it could be allocated latent identity marked detections. If a puma was dead on occasion k , it could not be allocated any latent identity detections.

Several process and observation models were described, so we detail below exactly which combinations we fit. Our model specifications were designed to test the relative importance of four items: (1) telemetry data from marked pumas, (2) sex as a categorical identity covariate for unmarked pumas, (3) activity center transiency for marked pumas between the marking and resighting processes, and (4) conSMR versus genSMR models. The influence of telemetry data was of particular interest, because the activity centers for four marked pumas likely relocated between marking and resighting, and we also had limited prior home range size data to inform camera-trap and cluster spacing. Therefore, we fit two genSMR models that included sex identity constraints for the resighting process, but differed as to whether telemetry data were incorporated or not (models 1 and 2). We extended models 1 and 2 to accommodate activity center transiency between the marking and resighting processes for marked pumas (models 3 and 4). Because models 3 and 4 best described the observed spatial dynamics of pumas during our study, we tested the importance of sex identity constraints by fitting these models without sex identity constraints (models 5 and 6). To test the importance of using genSMR over conSMR models, we fit models 1 and 2 excluding the marking process (models 7 and 8). Finally, to investigate if sex-specific detection function parameters were necessary to estimate puma density and the sex ratio, we fit a version of model 1 that included sex-specific detection function parameters (model 9).

We ran each genSMR model for 5×10^5 iterations, thinned by 75 iterations, and we discarded the first 5×10^3 iterations as burn-in. The large number of iterations was more than required for the models that excluded activity center transiency, but for models that included activity center transiency, σ^d mixed poorly and required many iterations to accurately characterize this posterior distribution. In contrast, we ran each conSMR model for 4×10^4 iterations and discarded the first 5×10^3 iterations as burn-in. We used data augmentation to augment the sample of marked pumas with up to $A = 250, 325\text{--}375$, and 600 hypothetical individuals that had all-zero detection histories for conSMR models, genSMR models that included telemetry data, and genSMR models that excluded telemetry data, respectively^{26,36,37,66}. We used the posterior modes for parameter point estimates, and we used the 95% highest posterior density intervals (HPDI) for interval estimates. We assessed precision of density estimates using the widths of 95% HPDIs and the posterior coefficients of variation (CV), or the posterior standard deviation divided by the posterior mode.

Ethics statement. Experimental protocols were approved by New Mexico Department of Game & Fish (per NMAC 19.35.6), Pueblo of Santa Ana Tribal Council, and a U.S. National Park Service Institutional Animal Care and Use Committee (IMR-VALL-Cain-LargeMammals-2015.A2). Data collection methods were carried out in accordance with standardized guidelines for humane wild mammal handling and welfare⁶⁷, scientific research permits (VALL-2017-SCI-0002 and VALL-2017-SCI-0049), and with explicit permission from relevant authorities.

Results

Marking and resighting. We deployed 30 live-traps, each for an average of 22 days (range: 2–64 days). We live-captured and marked 15 pumas (12 males:3 females); one marked female died of starvation prior to initiation of camera-trapping. We used a total of 190 telemetry locations ($n_{\text{males}} = 156$; $n_{\text{females}} = 34$) collected from GPS collars during the resighting period (mean = 14 locations/puma; range = 3–17). We acquired 68 unique detections of subadult and adult pumas at 31 camera-traps (46% of traps); the average number of detections per occasion was four (range: 1–7). Twenty (29%) camera-trap detections were of eight marked pumas (6 males:2 females); 17 spatial recaptures of marked pumas were obtained during the marking and resighting processes combined ($n_{\text{males}} = 15$; $n_{\text{females}} = 2$). Among the 48 detections of unmarked pumas, sex was definitively identified for 25 detections (52%; 10 male:15 female).

Population density and abundance. Puma population density point estimates ranged from 0.66 to 1.65 pumas/100 km², with the lowest estimates produced by conSMR models and the highest estimates produced by genSMR models that excluded telemetry data (Table 1). Integrating telemetry data approximately doubled σ^d estimates and decreased estimates of puma density in the genSMR models, whereas estimated puma density from conSMR models were similar regardless of whether telemetry data were used or not (0.66 versus 0.70 puma/100 km², respectively). The estimated number of unmarked pumas that were detected during resighting (n^{UM}) was between 18 and 26 individuals, with the smallest estimates from conSMR models (18–20 pumas) and the genSMR models that excluded telemetry data (20–22 pumas). The genSMR model that included telemetry data, activity center transiency, and sex as a partially identifying categorical covariate (model 3), which best explained the observed spatial dynamics of pumas during our study, estimated population density to be 0.84 puma/100 km² (95% HPDI: 0.50–1.28) with a CV of 0.24. This corresponded to an estimated population size

Table 1. Parameter estimates from generalized (Gen) and conventional (Con) spatial mark-resight models. Models with and without a categorical identity constraint for puma sex (Sex), telemetry data from GPS collars (Tel), activity center transiency between marking and resighting processes (Trans), and sex-specific detection functions (SS) were considered. Baseline detection rates for the marking (λ_0^M) and resighting (λ_0^R) processes, spatial scale of the detection function (σ^d ; km), spatial scale of activity center transiency (σ^t ; km), the number of unmarked pumas detected during resighting (n^{UM}), population density ($D = \text{puma}/100 \text{ km}^2$), and population size (N) were estimated. The 95% highest posterior density intervals (HPDI) are presented for D and N , as well as 95% HPDI width and coefficient of variation ($CV = SD/D$) for D . See Supplementary Table S2 for further details, including 95% HPDIs for all parameter estimates.

of 129 pumas (95% HPDI: 74–193) across the 15,314 km² estimation area, of which an estimated 26 unmarked pumas (95% HPDI: 18–32) were detected by camera-traps. Given those point estimates, 11.63% of pumas were marked and 22.81% of unmarked pumas were detected by camera-traps, indicating that we acquired spatial detection information for a combined 34.44% of pumas within S^G .

Density estimate precision. Modeling sex as a partially identifying categorical covariate for the detections of unmarked pumas improved precision of estimated density by 8%, reducing CV from 0.26 to 0.24 (model 5 versus model 3). Allowing activity center transiency for marked pumas between the marking and resighting processes improved precision of estimated puma density by 4% (based on CV), despite introducing more uncertainty into the process model via more complex model structure. Integrating telemetry data from GPS collars on marked pumas improved precision of estimated density by 17%, reducing CV from 0.29 to 0.24 (model 4 versus model 3); although, determining how much of the CV reduction resulted from a lower point estimate instead of a decrease in variance is difficult to disentangle.

Spatial scale of detection and activity center transiency. Estimates of σ^d from models that incorporated telemetry data ranged from 6.51 to 7.54 km, whereas estimates from models that excluded telemetry data ranged from 2.63 to 3.62 km. The smallest estimated σ^d was from the genSMR model that only included activity center transiency (model 6), whereas the largest σ^d was from the genSMR model that excluded activity center transiency but incorporated sex identity constraints and telemetry data (model 1). Estimated σ^t was 17.40 and 17.02 km from genSMR models that included both activity center transiency and telemetry data (models 3 and 5, respectively), but was just 0.35 and 2.71 km from genSMR models that excluded telemetry data (models 4 and 6, respectively). In models 4 and 6, σ^t was either not identifiable or was barely identifiable, so these considerably lower estimates are likely unreliable. Importantly, telemetry data from the GPS-collared pumas were critical to estimating σ^t , because the four individuals whose activity centers relocated between the marking and resighting processes were never detected by the camera-traps (Fig. 2).

Sex ratio. The genSMR model that included sex-specific detection functions (model 9) produced a similar population density estimate as the comparable genSMR model that had a pooled detection function (model 1). The estimated female and male σ^d from model 9 was 4.22 km (95% HPDI: 3.65–5.10) and 8.10 km (95% HPDI: 7.57–8.61), respectively, compared to the pooled estimate from model 1 of 7.54 km (95% HPDI: 7.06–8.12). The probability that a puma was female was 0.33 (95% HPDI: 0.16–0.49) and 0.34 (95% HPDI: 0.19–0.52) from models 3 and 9, respectively, which supports that sex-specificity of detection function parameters was unnecessary for accurately estimating the population sex ratio. The fact that the density and sex ratio estimates were nearly identical between models with and without sex-specificity suggests close to perfect compensation between λ_0^R and σ^d on the total exposure to detection⁶⁸. We note that with just two spatial recaptures for marked females, our female density and sex ratio estimates are largely dependent on how representative the telemetry data (i.e., movements) for the two marked females were of the entire female cohort within S^G .

Discussion

Previous puma mark-resight studies in the spatially explicit framework used conSMR models to estimate population density^{25–27}. If individual animals are live-captured to apply artificial marks, and this process occurs across the same area in which resighting will occur, marked individuals will on average likely reside closer to the resighting array than unmarked individuals³⁷. Modeling the marking process via genSMR models accounts for

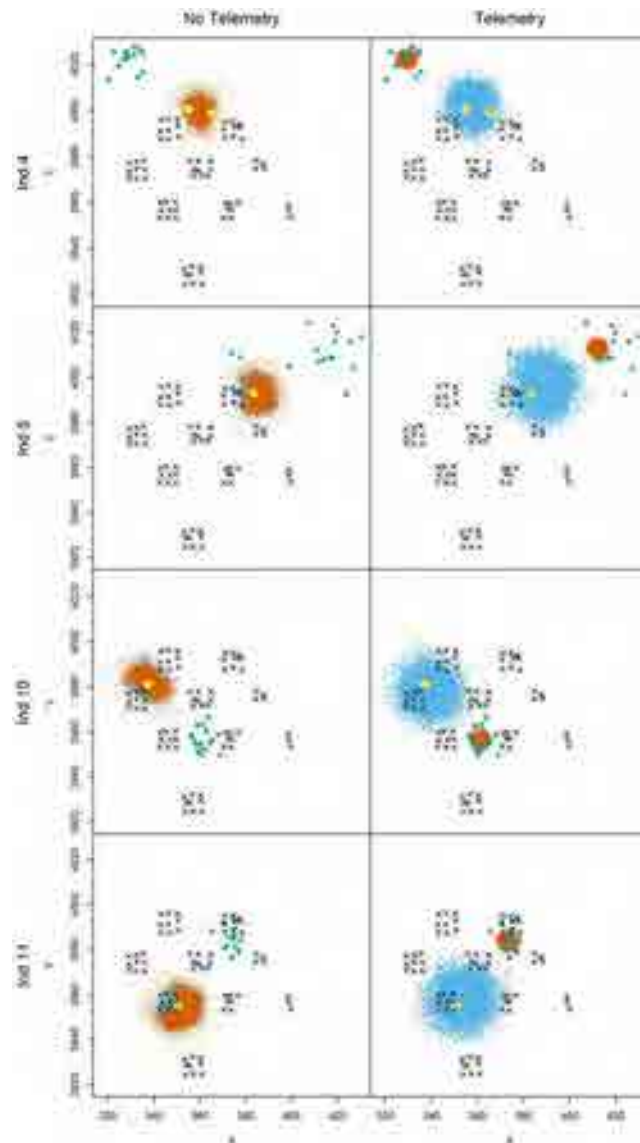

Figure 2. Estimated activity center locations for four marked pumas from generalized spatial mark-resight models that accommodated activity center transiency between marking and resighting processes, and excluded or included telemetry location data from GPS collars. The estimated posterior densities of individual activity centers for the marking and resighting processes are denoted by blue and orange, respectively. The spatial locations where each puma was live-captured, the locations of camera-traps, and thinned telemetry locations from the resighting period are denoted by yellow circles, black \times , and green circles, respectively. Image created by B.C.A. with the R statistical software⁶⁰.

these spatial patterns in activity centers, but conSMR models exclude the marking process and consequently may produce negatively biased density estimates^{37,39}. Indeed, our puma density estimates from conSMR models were ~17% lower than density estimated by our best genSMR model (model 3), chosen because of its most accurate characterization of the observed puma spatial dynamics (e.g., activity center transiency [through telemetry data] and spatial information about sex of unmarked pumas). Thus, our results support that genSMR models are preferable to conSMR models when the marking process involves live-capture and the marking and resighting arrays spatially overlap; particularly if researchers cannot assume that marked animals are uniformly distributed across the landscape, or the spatial distribution of marked animals is unknown and cannot be correctly specified.

Integrating telemetry data from GPS collars on marked pumas substantially improved parameter estimate precision and was critical for accurately estimating population density. First, the telemetry data allowed us to definitively determine individual identities from photograph detections. This was arguably more reliable than attempting to assign identities *ad hoc* based on researcher-perceived natural marks for a species that generally does not have unambiguous, individually unique physical features^{24–27}. Although researchers may be tempted to treat all pumas detected by camera-traps as unmarked and apply the ‘unmarked’ spatial capture-recapture model³⁴ to estimate population density, the large home ranges and generally low detection rates of pumas,

regardless of sampling method, will likely result in biased, imprecise, and unreliable density estimates from this model^{39,40}. Applying artificial marks to even a small portion of a population and using SMR models can greatly improve estimation of detection function parameters and population density^{26,34,36,37,39}.

Telemetry data also facilitated accurate estimation of σ^d , which our results suggest was substantially underestimated by the models that relied solely on camera-trap detection data (models 2, 4, and 6). To establish our clustered camera-trap design, we based simulations on parameter estimates from previously published spatially explicit puma density studies. Based on the σ that we used in simulations (5.0 km), we presumed that our camera-trap and cluster spacing were 0.70σ and $5.60\text{--}7.20\sigma$, respectively; however, based on the σ^d estimated by our best model (model 3), camera-trap and cluster spacing turned out to be 30% smaller ($0.54\sigma^d$ and $4.30\text{--}5.53\sigma^d$, respectively). If home ranges are large and detection rates are low ($\lambda_0 < 0.10$), detector spacing as small as 0.5σ may be too close to accurately characterize the true scale of animal movement within a single cluster^{43,45}. Estimated λ_0^R was < 0.10 among all of our considered models, and each of the nine clusters of camera-traps was considerably smaller than the average puma home range size derived from estimated σ^d , assuming a bivariate normal distribution¹⁹ (110.25-km² cluster size versus 799.23-km² home range size, based on model 3). Consequently, the full extent of individual puma space use likely could not be captured within a single cluster⁴⁵, which resulted in underestimation of σ^d and overestimation of puma density by the models that excluded telemetry data. Employing a wider camera-trap spacing of $1\text{--}2\sigma^d$ (6.51–13.02 km) within each cluster likely would have resulted in detections via the camera-traps alone that more accurately reflected the larger than expected puma space use⁴⁵. Although our spacing between clusters was well within the movement capabilities of pumas in the study area (based on estimated σ^d), a wider camera-trap spacing within clusters would also decrease the distance between clusters, which might have the added benefit of increasing the number of spatial recaptures^{43,45}.

An alternative but unlikely explanation for the smaller σ^d and higher puma density estimates from models that excluded telemetry data could be that the marked pumas were not a random sample of the population, but were instead representative of a cohort of pumas that had larger than average home ranges³⁶. Subadult male pumas are generally transient and typically have the largest home ranges among all sex-specific cohorts of puma populations⁶⁹. We live-captured and marked both subadults and adults and both males and females, however, and although just 20% of our marked pumas were females, genSMR model results suggested that only 33–34% of the population was female. Furthermore, the point and interval estimates of puma density from the genSMR model with sex-specific detection function parameters (model 9) were nearly identical to the analogous model with detection function parameters pooled between sexes (model 1). This strongly supports that a sex imbalance among marked individuals was not a source of incongruous σ^d estimates between models that included and excluded telemetry data, thereby indicating that density estimates from the genSMR models that integrated telemetry data more accurately reflected puma space use during our study.

A third reason supporting the importance of telemetry data, and a primary reason why the transient activity center model improved density estimation, was to accurately estimate activity center locations for the pumas who relocated considerable distances between the marking and resighting processes. Efford and Hunter³⁵ raised concerns about the potential for such activity center transiency between observation processes to influence SMR model parameter estimates, but those authors had no independent data to test for this. In contrast, the telemetry data that we had from marked pumas allowed us to document and model large activity center relocations between processes. Because the four marked pumas who relocated were not detected by camera-traps, the resighting data provided little information about whether or not those individuals' activity center locations moved, and if so, how far. Although two pumas (individuals 10 and 11) moved to areas of the camera-trap array where they likely had similar detectability as the locations at which they were live-captured and marked, two other pumas (individuals 4 and 5) moved to areas where they were effectively undetectable by all camera-traps (Fig. 2). In model 1, which did not accommodate activity center transiency, the distances between live-capture locations and the estimated activity center locations, which were primarily informed by the telemetry data, were larger than reality. This inflated the σ^d estimate (7.54 versus 6.51 km from models 1 and 3, respectively), which in turn decreased the λ_0^R and λ_0^M estimates. These differences in detection function parameters corresponded to a ~12% difference in puma density point estimates (0.94 versus 0.84 puma/100 km²), suggesting that accommodating activity center transiency may be important for reliably estimating population density in SMR studies. Additionally, σ' was substantially underestimated without the telemetry data, because all four major movements were not discernable from the camera-trap data; this caused poor estimation of those pumas' activity center locations and introduced bias into detection function and density parameter estimates. Thus, having considerable telemetry data likely will lead to a more robust application of SMR models, informing if activity center transiency needs to be accommodated in the model structure to improve parameter estimation.

Fully transient activity centers have been considered in conSMR models⁶¹, but our study is the first application of a single activity center transition that was used to explain observed animal movement dynamics. The base genSMR model provides an adequate description of the distribution of marked and unmarked individuals if they do not relocate between the marking and resighting processes; if individuals randomly relocate between processes, which is unlikely, the spatial uniformity activity center model may be appropriate. Accommodating activity center transiency as we did results in an intermediate activity center model in which individuals are not at exactly the same spatial location between processes and the similarity of locations is determined by the σ' parameter. However, if individual animals exhibit multiple substantial movements during observation processes, an activity center model that accommodates fully transient activity centers might be more appropriate^{61,62}. Nevertheless, distinguishing between a process model with stationary activity centers and a large σ^d value and a model with transient activity centers and a small σ^d value will be difficult without considerable telemetry data, given the sparsity of typical capture-recapture and mark-resight detection data.

Despite the relatively small improvement in density estimate precision from using sex as a categorical identity covariate compared to the substantial improvement from incorporating telemetry data, using categorical identity covariate data that is available from camera-trap detections has considerable promise. The 8% precision improvement that we observed by using sex of unmarked pumas comes from data that has not been used in SMR models to date, but ecologists and managers should be interested in extracting as much precision out of detection data as possible. Additionally, sex was a single categorical identity covariate that we confirmed for only approximately half of the detections of unmarked pumas. Other populations of pumas or other wildlife species may provide more categorical identity covariate information from photographs; for example, the natural marks used by previous studies to attempt to assign individual identities for estimating population density^{24,25,27,61,70} could instead be treated as categorical identity covariates, allowing for the possibility that more than one individual in a population has a similar physical feature. This would obviate the requirement that potentially erroneous individual identities are assigned, but it may also reduce the precision of density estimates, perhaps appropriately, depending on the accuracy of categorical identities assigned by observers.

We acknowledge that using GPS collars as the primary mark can be expensive, but our results indicate that the realized and potential benefits of marking a portion of a population with GPS collars outweigh the costs. Clearly, integrating telemetry data in spatially explicit analyses can substantially improve estimation of the spatial scale parameter, activity center locations, and population density, as also noted by previous studies^{26,36,37,39}. Furthermore, by marking a portion of animals with GPS collars, which are typically functional for multiple years, additional demographic and ecological information that are important to conservation and management can be obtained, effectively constituting SMR as a population ecology research approach. This includes data on survival and cause-specific mortality, home range size, and resource selection^{71,72}, as well as seasonal and annual variation in population density if camera-traps are active across seasons and years, respectively. Additionally, if population genetics are of interest, genetic samples can be collected when animals are captured for marking. If study budgets are limited, a cheaper alternative may be to mark some animals with GPS collars and others with only ear tags or non-GPS collars that have visually unique numbers or patterns that can be identified from photographs. For example, Whittington *et al.*³⁷ GPS-collared some individuals, only ear-tagged others, and used camera-traps and genSMR models to precisely estimate brown bear (*Ursus arctos*) population density.

Pumas occupy tens to hundreds of thousands of square kilometers within most jurisdictions across their extant range^{1,69,73}. In general, precision and accuracy of spatially explicit population density estimates for wide-ranging large carnivores improve with increasing study area size^{44,45,74}. By deploying camera-traps in a systematic cluster design with gaps between clusters where no cameras existed, we were able to use a small number of camera-traps to estimate puma density for a 15,317-km² area. This area was five-fold larger than the average spatial extent among all previous puma density studies that also used spatially explicit models (mean = 2,849 km²; range: 215–8,800 km²), and our density estimates were among the most precise estimates that have been produced for pumas to date ($CV_{[genSMR]} = 0.24–0.31$; Table 2). Therefore, clustered camera-trapping in an SMR framework can facilitate efficient and reliable estimation of puma population density at the broad regional scales that conservation and management typically occur. For example, endangered Florida panthers (*P. c. coryi*) reside within a ~16,000-km² area that encompasses multiple patches of suitable habitat⁷⁵, and a portion of panthers are annually captured and collared^{26,76}. Applying clustered camera-trapping across that entire area and using genSMR models to analyze detection data could result in the first range-wide spatially explicit estimates of Florida panther population density and abundance, with little additional effort compared to other available puma sampling approaches in the spatially explicit framework. Our sampling and analytical combination is likely also applicable to other terrestrial mammals that similarly lack individually unique natural markings. For instance, obtaining reliable population density and abundance estimates for imperiled Mexican gray wolves (*Canis lupus baileyi*) and red wolves (*C. rufus*) is important to their recovery, and individual wolves in those populations are routinely monitored via radiocollars that could serve as effective marks. Nevertheless, we agree with other studies that suggested researchers should use simulation to develop study area- and species-specific survey designs prior to deploying camera-traps^{43,45,74}. Having home range size data beforehand to inform camera-trap and cluster spacing would be ideal⁴⁵, but if such data are unavailable, our results support that marking a portion of animals with GPS collars and integrating their telemetry location data in spatially explicit models can serve as insurance if detector spacing turns out to be insufficient³⁶.

Our study provides the first spatially explicit population density estimates for pumas in the semi-arid to arid southwestern United States, where hot summer temperatures, high ultraviolet radiation, and generally limited winter snow cover may impede effectiveness of, or preclude, scat detection dog and biopsy dart sampling of pumas. Regardless of model specification, all of our puma density estimates were within the range of reported spatially explicit estimates for the species, but density estimated by our best model (0.84 puma/100 km²) was towards the lower bound of that range (Table 2). Estimates acquired using the biopsy dart and scat detection dog methods may not be directly comparable to our estimates, however, because estimates from those techniques might be inflated as a result of including dependent juveniles in the detection histories^{20,23}, whereas our estimates pertain solely to independent pumas. Nonetheless, the majority of our study area was characterized as high quality puma habitat relative to elsewhere in the Southwest⁷³; thus, our estimates suggest that the Southwest might commonly support pumas at lower densities than ecosystems in the Northwest and Northern Rockies regions^{20–24,51}. Additional research is needed to evaluate the influence that legal harvest of pumas and prey availability and distribution may have on seasonal and annual variation of puma population density in our study area and across the Southwest in general.

Table 2. Study locations, sampling methods, model types, and parameter estimation areas (km²) for studies that used spatial capture-recapture (SCR), conventional spatial mark-resight (conSMR), or generalized spatial mark-resight (genSMR) models to estimate puma population density (puma/100 km²), ordered by sampling methods and model types. Methods included biopsy darting (BD), snow-backtracking (SB), scat detection dogs (SD), regular camera-trapping (RC), clustered camera-trapping (CC), dead recoveries (DR), and telemetry locations from GPS collars (TL). Coefficient of variation (CV), standard errors, or standard deviations were not reported by multiple studies (—), so we also present 95% interval widths for comparing precision of density estimates. Densities are presented as the ranges of point estimates. *Average among multiple study areas; †excludes one density estimate for which variance of the corresponding spatial scale parameter (σ) was inestimable.

Data Availability

All data generated for analysis and all R code of MCMC algorithms for reproducing the analysis are available from the PANGAEA® digital repository, <https://doi.org/10.1594/PANGAEA.897113>. Data were made available under provisions of the State of New Mexico Inspection of Public Records Act (1978 NMSA 14.2).

Research Summary 2018-2021

Estimating Cougar Density and Population Size in New Mexico using Spatial Mark-Resight Models

Background

In 2017, the Department implemented a study using a novel approach for estimating cougar population densities using GPS tracking collars, trail cameras, and advanced, Spatial Mark-Resight models. These models incorporated data from the capture process, recaptures via trail camera photos, and weekly GPS locations. The findings from that 2017 study were published by Murphy et al. (2019), and were incorporated into a harvest limit adjustment for Cougar Management Zone (CMZ) F, where the study was conducted.

We used that methodology for an expanded study in CMZs B and F in 2018, to estimate population size across both zones where localized population dynamics were expected to be occurring. Harvest limits were again adjusted in 2019 based on the findings of that 2018 study, and CMZs B and F were combined into one zone (CMZ B). In 2019, the Department began another study using the same methods in CMZ Q, which was concluded by August 2021. The results from this study were used to inform the proposed changes for the 2023 Bear and Cougar Rule development process. Recognizing the novelty of these field and analytical methods for a cryptic species like cougar, and their use across a large area, the Department worked with independent statisticians to review these models.

We present in this report a brief summary of the findings of those efforts. An in-depth description of the field methodology and analytical techniques can be found in the Murphy et al. (2017) publication, and will be described further in publications by the Department as we continue to implement, adjust and assess this approach across multiple years and study areas throughout the state.

Results and Analysis of the Study in CMZs B and F, 2018

The study in CMZs B and F occurred from May through November, 2018. We deployed 109 camera sites across 15 grids in GMUs 4, 5A/B, 6A/B/C, and 51A/B. During that time, there were 14 cougars fitted with GPS collars, 146 photo captures of cougars, and no mortalities.

We used a model that incorporated GPS data, flexibility for activity centers to shift, and sex-specific differences in detection parameters to estimate for the study area a population size of 124 (79 – 169) independent-aged cougars and population density of 0.70 (0.45 – 0.96) independent-aged cougars per 100 km².

In 2022, we then assessed the models from Murphy et al. (2017) under a simulation-based framework to understand how sampling effort affects model precision, and validate model accuracy and precision. This approach used a simulated population and simulated data generated with information from the models of our observed data for CMZs B and F to examine how the model performed estimating for a known population size with a dataset similar to ours. These results aligned well with the models from our observed dataset in generating estimates with similar accuracy and precision (Figure 1).

We then tested simulated capture data sets with low, normal, or high number of marked animals, or a low, normal or high number of recaptures. This allowed us to assess how the model performed under different scenarios with fewer or more marked animals on the landscape, or fewer or more detections of marked animals on cameras. In general, there was relatively little bias to abundance estimates with changes to marking and resighting, and increases in accuracy and precision that levelled off within range of mark and resight probabilities of our observed data (Figure 2). These simulations provided insight on general impacts that would occur over the entire estimation area if these conditions were homogenous across all individuals and cameras.

Figure 1. Abundance estimates for a simulated data set for a simulated population ($N=100$), from Spatial Mark Resight models using GPS collar data (Models 1 and 2), and without GPS collar data (Model 3).

Figure 2. Changes in model precision with increasing probabilities of marking an individual (lam0.mark) and increasing probabilities for recapturing (lam0.sight) via trail cameras individuals for Spatial Mark Resight models using GPS collar data (Models 1 and 2) and without GPS collar data (Model 3).

We also took a closer look at the spatial distribution of the data, which suggested it could be impacting estimates. Generally for spatial capture recapture models, when there are no detections at a detector or an entire grid the model assumes a lower density than what may be observed at detectors where individuals are regularly detected, or assumes no individuals occur there, and assumes an averaged density as you move away from detectors in general (Royle et al. 2014). The implications of this are that site selection and camera placement may impact density estimates. If the reason for a lack of detections is poor site selection or camera placement, and as a result there are no detections of cougars where it is known that they occur, then the models will estimate lower densities in that area. We can see in our data there are grids that had few to no photo detections, but where we know cougars were present from GPS data for collared individuals (Figures 3 and 4).

Figure 3. Distribution of trail camera photo 'recaptures' of cougars in Cougar Management Zones B and F, New Mexico, 2018.

Figure 4. Distribution of GPS locations from cougars used in density estimation for Cougar Management Zones B and F, New Mexico, 2018.

Additionally, we have made some initial investigation into the impact of the spatial arrangement of GPS collared individuals through data augmentation of this data set. We removed GPS and marking data for individuals that had home ranges overlapping with another collared individual, and found that with no data showing home range overlap the model estimates of density were lower than when your data did include individual's whose home ranges overlap (Figure 5). Home range overlap is expected with our sampling because we captured both males and females which tend to have overlapping home ranges between the sexes. Home range overlap between individuals of the same sex is less common.

Figure 5. Abundance estimates for the data from Cougar Management Zones B and F, 2018, when the data is augmented to remove individual's whose spatial distribution overlapped another individual's.

Results of the Study in CMZ Q, 2019-2021

In 2019 we used the same methodology to estimate cougar population density in CMZ Q, across GMUs 28, 29, 30, and 34. Captures and camera deployment began in 2019, and we analyzed the data collected at 119 camera sites from April 2020 to December 2020 (weeks 67-101 of the study). During that time, there were 18 cougars that were GPS collared, 368 photo captures, and three mortalities which were accounted for by censoring those individuals.

We estimated density and population size for the study area using a model that incorporated GPS locations and sex differences in the detection parameters, but did not include flexibility for activity centers to shift because we did not include data on the capture process. We estimated a density of 0.56 (0.47-0.64) independent-age cougars per 100 km², and a population size for the study area of 116 (98-134) independent-age cougars.

Figure 5. Distribution of estimated activity centers across the state space from Spatial Mark-Resight model estimation of cougar density in Cougar Management Zone Q, New Mexico, 2020.

ABSTRACT Considering advances in noninvasive genetic sampling and spatially explicit capture–recapture (SECR) models, the New Mexico Department of Game and Fish sought to update their density estimates for American black bear (*Ursus americanus*) populations in New Mexico, USA, to aide in setting sustainable harvest limits. We estimated black bear density in the Sangre de Cristo, Sandia, and Sacramento Mountains, New Mexico, 2012–2014. We collected hair samples from black bears using hair traps and bear rubs and used a sex marker and a suite of microsatellite loci to individually genotype hair samples. We then estimated density in a SECR framework using sex, elevation, land cover type, and time to model heterogeneity in detection probability and the spatial scale over which detection probability declines. We sampled the populations using 554 hair traps and 117 bear rubs and collected 4,083 hair samples. We identified 725 (367 male, 358 female) individuals. Our density estimates varied from 16.5 bears/100 km² (95% CI = 11.6–23.5) in the southern Sacramento Mountains to 25.7 bears/100 km² (95% CI = 13.2–50.1) in the Sandia Mountains. Overall, detection probability at the activity center (g_0) was low across all study areas and ranged from 0.00001 to 0.02. The low values of g_0 were primarily a result of half of all hair samples for which genotypes were attempted failing to produce a complete genotype. We speculate that the low success we had genotyping hair samples was due to exceedingly high levels of ultraviolet (UV) radiation that degraded the DNA in the hair. Despite sampling difficulties, we were able to produce density estimates with levels of precision comparable to those estimated for black bears elsewhere in the United States. © 2018 The Wildlife Society.

KEY WORDS American black bear, capture–recapture, density estimation, DNA degradation, New Mexico, *Ursus americanus*.

State agencies spend a large portion of their annual budget estimating abundance and population trends of game animals, in part, so they can set sustainable harvest levels. Survey methods for large ungulates are well-developed and can provide relatively robust estimates of abundance for common game species such as deer (*Odocoileus* spp.) and elk (*Cervus canadensis*; Bleich et al. 2001, Zabransky et al. 2016). In contrast, estimating the abundance or density of large carnivores such as American black bears (*Ursus americanus*; hereafter, black bears) is more difficult because their cryptic behavior and low population densities make common survey methods used for large ungulates (e.g., aerial counts)

ineffective because of low detection rates (Miller 1990, Obbard et al. 2010). Historically, many state agencies set harvest limits for carnivores based on harvest data, including sex ratio and age structure of the harvested animals, which can be used to infer harvest effects on a population (Garshelis 1990, Hristienko and McDonald 2007). Yet, hunter selectivity and sex-specific vulnerability may influence harvest composition (Miller 1990, Beston and Mace 2012).

In New Mexico, USA, as in other parts of the American Southwest, black bears inhabit forested mountain ranges separated by desert and grassland valleys resulting in fragmented populations with varying degrees of connectivity (Atwood et al. 2011). Prior to their designation as a game species in 1927, the statewide black bear population was reduced to 660 owing to unlimited hunting and government sponsored anti-predator programs (New Mexico Department of Game and Fish [NMGFD] 1926). With legislative

¹E-mail: mjgould4@gmail.com

protection in place, the statewide population increased to 3,000 animals by the mid-1960s (Lee 1967). For nearly 20 years, this population estimate, paired with hunter harvest data, was the basis for setting harvest limits by the NMDGF. However, uncertainty in trends in black bear abundance during the late 1980s resulted in NMDGF initiating a decade-long study of black bear ecology in the 1990s (Costello et al. 2001).

New Mexico's most recent density estimates for black bear were derived from Costello et al. (2001) by dividing the minimum population size that was calculated using population reconstruction, which counts the number of individuals known to be alive during the study based on known age, by the effective trapping area (Dice 1938, Wilson and Anderson 1985, Eberhardt and Knight 1996). Their minimum density estimates were 17.0 bears/100 km² for the more mesic Sangre de Cristo Mountains in northern New Mexico and 9.4 bears/100 km² for the more xeric Mogollon Mountains of west-central New Mexico with intermediate habitat conditions being assigned a density equal to the mean of these 2 density estimates (i.e., 13.2 bears/100 km²). Using a habitat suitability model, the NMDGF extrapolated these density estimates to similar land cover types throughout New Mexico. This extrapolation served as the basis for statewide estimates of abundance for black bears that were then incorporated into a population projection model to monitor abundance and its trend in each Bear Management Zone (BMZ).

Innovations in non-invasive genetic sampling techniques (NGS; Woods et al. 1999), coupled with robust statistical analyses such as spatially explicit capture–recapture (SECR; Efford 2004), have provided researchers with improved tools to estimate the abundance and density of carnivore populations from which harvest limits can be established. These tools have facilitated monitoring efforts and produced density estimates for black bear populations across much of their range (Stetz et al. 2014, Hooker et al. 2015, Sun et al. 2017).

Considering advances in NGS and SECR models, the NMDGF sought to update their density estimates for New Mexico black bear populations. Our objectives were to estimate the density of black bears in primary bear habitat within 7 of the 14 BMZs in New Mexico.

STUDY AREA

The 7 BMZs were encompassed by 5 study areas located in the northern (NSC; 6,400 km²) and southern (SSC; 3,525 km²) Sangre de Cristo, Sandia (300 km²), and northern (NSacs; 925 km²) and southern (SSacs; 2,775 km²) Sacramento Mountains, New Mexico (Fig. 1). We sampled the Sandia Mountains in their entirety because of their smaller size. The 2 BMZs located in the NSC and the 2 in the SSacs are managed by NMDGF using the same estimate of density. Thus, we only report density for 5 study areas instead of 7 BMZs. Sampling within each study area was limited to primary bear habitat, which is defined as closed-canopy forest and woodland cover types (Fig. 1; Thompson et al. 1996, Costello et al. 2001). All 5 study areas

Figure 1. Primary American black bear habitat in New Mexico, USA highlighting the northern (NSC) and southern (SSC) Sangre de Cristo, Sandia, and northern (NSacs) and southern (SSacs) Sacramento Mountains study areas.

were managed as multiple-use forests by federal and state agencies and private landowners encompassing portions of 4 National Forests, 6 wilderness areas, and 25 parcels of private land. The topography was diverse for each mountain range and maximum elevation was 4,011 m, 3,254 m, and 3,649 m for the Sangre de Cristo, Sandia, and Sacramento Mountains and minimum elevation was approximately 1,900 m, 1,700 m, and 1,500 m, respectively. The Southern Rocky Mountains floristic district characterized the Sangre de Cristo Mountains, whereas the Mogollon floristic district characterized the Sandia and Sacramento Mountains. Dominant vegetation types in the study areas included oak-mountain mahogany (*Quercus* spp.–*Cercocarpus* spp.) scrublands, piñon pine-juniper (*Pinus edulis*–*Juniperus* spp.) woodlands, ponderosa pine (*P. ponderosa*), white pine (*P. monticola*), Douglas fir (*Pseudotsuga menziesii*), aspen (*Populus tremuloides*), Engleman spruce-subalpine fir (*Picea engelmannii*–*Abies lasiocarpa*) mixed-forest, and bristlecone (*P. aristata*) and limber (*P. flexilis*) pine forests (Costello et al. 2001). Important mast-producing species included oak, piñon pine, juniper, red barberry (*Mahonia haematocarpa*), chokecherry (*Prunus virginiana*), gooseberry (*Ribes* spp.), alpine cancer-root (*Conopholis alpina*), cactus (*Opuntia* spp.), and sumac (*Rhus* spp.; Kaufmann et al. 1998, Costello et al. 2001). The average monthly temperature was highest in July across the Sangres (24–29°C), Sacramentos (22–29°C) and Sandias (33°C), and lowest in January across the Sangres

(-15°C to -8°C), Sacramentos (-7°C to -5°C), and Sandias (-5°C ; Western Regional Climate Center 2017). The average monthly precipitation was highest during the monsoon season (Jul–Oct) with rainfall peaking in August across the Sangres (7.10–8.15 cm), Sacramentos (7.62–12.70 cm), and Sandias (5.3 cm; Western Regional Climate Center 2017). Other common predators in the study areas included mountain lion (*Puma concolor*), bobcat (*Lynx rufus*), coyote (*Canis latrans*), gray fox (*Urocyon cinereoargenteus*), and common ungulates included elk, mule-deer (*Odocoileus hemionus*), white-tailed deer (*O. virginianus*), Rocky Mountain bighorn sheep (*Ovis canadensis*), and exotic barbary sheep (*Ammotragus lervia*).

METHODS

Field Sampling and Genetic Analysis

We used hair traps (Woods et al. 1999) and bear rubs (Kendall et al. 2008) concurrently to sample each black bear population. We set hair traps and bear rubs across 4 sampling occasions in the NSC (22 Apr–5 Sep 2012) and SSC (29 Apr–9 Sep 2013) and across 6 sampling occasions in the Sandias, NSacs, and SSacs (5 May–6 Aug 2014). Because of logistical constraints, sampling occasions in the NSC and SSC lasted 4 weeks, whereas sampling occasions for the Sandias, NSacs, and SSacs were 2 weeks. We distributed a grid of 5-km \times 5-km cells across the landscape with a randomly determined origin. Within each cell, we set a single hair trap. We located trap sites based on suspected travel routes, occurrence of seasonal forage (e.g., newly emergent green grass and ripe soft and hard mast), and presence of bear sign (Fig. 2; Figs. S1 and S2, available online in Supporting Information). A hair trap consisted of a single strand of barbed wire wrapped around ≥ 3 trees at a height of 45 cm, with a lure pile constructed from woody debris at the center (Woods et al. 1999). During each sampling occasion in the NSC and SSC, we randomly selected and applied 1 of 4 non-consumable lures (cow blood and fish emulsion mixture, anise oil, fatty acid scent tablet, or skunk tincture and lanolin mixture) to the lure pile to attract bears. A chi-square test of independence showed that the 4 lures were not collecting similar proportions of hair samples ($\chi^2_3 = 616.29$, $P \leq 0.001$); thus, we discontinued the use of anise oil and fatty acid scent tablets in the Sandia and Sacramento Mountains. A sample consisted of all hair caught in one barb. Bears will also roll around in the lure pile depositing hair. We used our best judgement to define hair samples in the lure pile that we believed originated from a single individual. We deposited each hair sample in a separate paper coin envelope and incinerated any remaining hair with a propane torch to prevent false recaptures. We moved hair traps (100 m to 2.5 km) each occasion to increase novelty and recapture rates (Boulanger and McLellan 2001, Boulanger et al. 2004).

Bears rub on a myriad of objects including trees and power poles (Burst and Pelton 1983, Kendall et al. 2008). We opportunistically identified and collected hair from bear rubs along trails used en route to hair traps. We identified bear rubs using evidence of rubbing behavior such as a smoothed

surface with snagged hair. We attached 3 to 4 short, vertical strands of barbed wire to the rub object covering the area of rubbing to collect discrete hair samples (Kendall et al. 2008, 2009; Stetz et al. 2014). We identified rubs at varying time intervals across sampling occasions, but once established we monitored them concurrently with nearby hair traps. We collected hair samples only from the barbed wire to ensure that the samples collected were from individuals that visited the rub during the sampling occasion. Hair collection protocols for bear rubs were identical to hair traps, and we stored all hair samples in an airtight container on silica desiccant at room temperature.

We genotyped each hair sample using 8 polymorphic microsatellite loci (G1D, G10B, G10L, G10M, G10H, G10J, G10U, MU59; Paetkau et al. 1995, 1998; Taberlet et al. 1997). We also used the ZFX-ZFY marker to identify sex (Durnin et al. 2007). We selected specific markers for individual identification by ensuring that the mean expected heterozygosity for each marker was between 0.70 and 0.80 (Paetkau 2003, 2004). These markers were determined from an initial subsample from the NSC population in 2012. All hair samples were genotyped by Wildlife Genetics International in Nelson, British Columbia, Canada (WGI; Paetkau 2003, Kendall et al. 2009).

Technicians screened samples for suitability before analysis. First, they eliminated samples that contained insufficient genetic material for analysis (no root, < 1 guard hair, or < 5 underfur hairs) or appeared to be from heterospecifics. Next, they used the ZFX-ZFY marker as a prescreen to remove low-quality hair samples that were likely to fail during the multilocus genotyping phase. After the prescreen, technicians amplified the 9-candidate markers for each sample. They eliminated samples that amplified ≥ 3 alleles at 1 marker (indication of a mixed sample) or failed to amplify ≥ 3 loci. They reamplified the samples that failed at < 3 loci, resulting in either a full 9-locus genotype or a discarded sample. They examined pairs of samples that were mismatched at 1 or 2 markers for evidence of amplification or human error. Technicians reamplified any mismatched pair under the assumption that genotyping error may have created the similarity between the 2 samples (Paetkau 2003). If 1 or 2 mismatched pairs remained between samples, we concluded the 2 samples were from separate individuals. We assigned an individual identification number to each sample with a unique multilocus genotype based upon the unique catalogue code from the first sample to identify the individual's genotype. Given each study area is not an isolated population, we calculated the expected and observed heterozygosity for each mountain range using program GENPOP (Raymond and Rousset 1995, Rousset 2008; www.genepop.curtin.edu.au, accessed 15 Mar 2016).

Density Estimation

We used SECR models (Efford 2004, Borchers and Efford 2008) implemented in the R software package secr (v. 2.9.5 and 2.10.4; Efford 2015, 2016) to estimate 3 parameters in separate analyses for each study area: density (D), detection probability of an individual at its activity center (g_0), and the

Figure 2. Primary American black bear habitat identified by Costello et al. (2001) overlaid with hair traps and bear rubs set for the northern (NSC) and southern (SSC) Sangre de Cristo Mountains, New Mexico, USA, 2012–2013.

spatial scale over which detection probability declines as the distance between an individual's activity center to the detection device increases (σ). We used a half-normal detection function for our observation model and a homogeneous Poisson distribution as our state model, which assumes latent activity centers are distributed evenly across the landscape (Efford et al. 2009). Spatially explicit capture–recapture also requires a habitat mask. The habitat

mask is the area of integration (i.e., area of interest that contains all possible latent activity center locations) and includes all animals with a non-zero probability of detection (Ivan et al. 2013). Individuals may reside beyond the habitat mask, but they have a negligible probability of detection (Borchers and Efford 2008, Royle et al. 2014). We generated the habitat mask by buffering the sampling detectors in the NSC, SSC, Sandias, NSacs, and SSacs by 18.75 km,

25.40 km, 13.23 km, 14.84 km, and 11.03 km, respectively, which we derived from the capture data using the suggest. buffer function (Efford 2016). Within our habitat mask, we limited our density estimates to primary habitat as identified by Costello et al. (2001) for black bears in New Mexico. Variability in sampling effort may negatively bias density estimates and reduce the ability to explain variation in detection probability, so we accounted for variable sampling effort by using the number of days each sampling detector was active (Efford et al. 2013).

Predictors of g_0 and σ included time (t ; 4 or 6 sampling occasions depending on the study area), sex, elevation (elev), detector type (type; hair trap vs. bear rub), and 5 land cover categories (cover). We chose time and sex as covariates because detection probability and movement patterns may fluctuate over the sampling period and differ between males and females (Sawaya et al. 2012, Stetz et al. 2014). We selected elevation and land cover to represent the spatial heterogeneity of black bear food resources because this heterogeneity could influence g_0 and σ depending on food availability and distribution (Rovang et al. 2015). We did not include land cover type and elevation in the same model because a box plot of elevation by land cover type revealed that these variables were not independent. We then conducted a 1-way analysis of variance that indicated within each study area elevation significantly differed among land cover types (NSC: $F_4 = 618.02$, $P \leq 0.001$; SSC: $F_4 = 367.14$, $P \leq 0.001$; Sandias: $F_1 = 7.39$, $P = 0.008$; NSacs: $F_2 = 278.06$, $P \leq 0.001$; SSacs: $F_2 = 582.95$, $P \leq 0.001$). Within each study area, *post hoc* pairwise comparisons of elevation across land cover types were also significant (Tukey-Kramer test, $P \leq 0.01$ for all comparisons). We extracted elevation for each detector using the National Elevation Dataset 30-m resolution digital elevation model (www.nationalmap.gov, accessed 10 May 2015). We standardized elevation by subtracting the mean from each observation and dividing by 1 standard deviation (Gelman and Hill 2007).

We extracted land cover using the Interagency Landfire Project (Rollins 2009; www.landfire.gov, accessed 10 May 2015) land cover classification at 30-m spatial resolution. We combined 6 land cover classifications into 5 categories: aspen-conifer, mixed conifer (combination of Douglas fir and white pine), piñon pine-juniper, ponderosa pine, and spruce-fir. Variation in the abundance and distribution of each land cover class across the study areas resulted in a different number of categories and, consequently, a different number of parameters modeled for each study area. Aspen-conifer and spruce-fir were included only in the NSC and SSC. Mixed-conifer was included in all study areas except the Sandia Mountains. Piñon pine-juniper and ponderosa pine were included in all study areas. We visually assessed and assigned the dominant land cover classification surrounding the location of each detector using ArcGIS 10.2.1 (Environmental Systems Research Institute [ESRI], Redlands, CA, USA).

We modeled g_0 and σ concurrently by fitting a model where both parameters varied by elevation, land cover, or

time. We also included models that varied by time for g_0 and land cover for σ ($g_0 \sim t$, $\sigma \sim \text{cover}$), time for g_0 and elevation for σ ($g_0 \sim t$, $\sigma \sim \text{elev}$), land cover for g_0 and time for σ ($g_0 \sim \text{cover}$, $\sigma \sim t$), and elevation for g_0 and time for σ ($g_0 \sim \text{elev}$, $\sigma \sim t$). We also constructed models for g_0 and σ with time in an additive relationship with each covariate ($g_0 \sim t + \text{covariate}$, $\sigma \sim t + \text{covariate}$). We included additive effects because g_0 and σ are likely to vary because the black bear mating season occurs during the late-spring and early summer, when male bears might be expected to move more than females; because hyperphagic foraging behavior occurs during early fall, when all bears move more to find food; and because the distribution of food varies across the period when bears are active (e.g., grasses green-up in the spring and mast ripens in the late summer and fall). We also ran each model with the addition of an animal by site learned response (bk) for g_0 ($g_0 \sim \text{covariate}(s) + \text{bk}$) because density estimates can be severely biased when a behavioral response occurs in the presence of missing data (e.g., hair samples that failed to amplify a complete genotype; Augustine et al. 2014). However, we believe we mitigated a behavioral response by moving hair traps and randomly applying lures between sampling occasions, and Murphy et al. (2016) reported negligible bias to SECR-based density estimates in such a scenario. Thus, our inclusion of the bk parameter was a precautionary measure.

We modeled density as a function of sex to investigate for an uneven sex ratio (Tredick and Vaughan 2009, Sun et al. 2017). We did so by selecting the top ranked model from each study area and comparing that model to another with the same detection submodel but with density as a function of sex. We did not use land cover type or elevation as predictors of density because black bears track the spatiotemporal variability of food resources resulting in a fluid use of the landscape (Costello and Sage 1994, Sun et al. 2017). Also, because the New Mexico black bear hunting season occurs from mid-August to November, the seasonal distribution of black bears may change from summer to fall. Consequently, fall harvest regulations based on the variation in density of black bears across land cover types during the summer would be inappropriate. This enabled us to estimate density in a way that would be most conducive to the current management system employed by the NMDGF, which was a single density estimate for each study area given the large extent and heterogeneous landscape encompassed by the BMZs.

We could not fit 4 models for the NSC because the computer we used for analysis was unable to allocate enough memory to initialize all models. The 4 models were when g_0 and σ were modeled concurrently with elevation (i.e., $g_0 \sim \text{elev}$, $\sigma \sim \text{elev}$), concurrently with time and elevation (i.e., $g_0 \sim t + \text{elev}$, $\sigma \sim t + \text{elev}$), and with time and elevation for different parameters (i.e., either $g_0 \sim t$, $\sigma \sim \text{elev}$ or $g_0 \sim \text{elev}$, $\sigma \sim t$). We also excluded detector type in our model set for the NSacs because only 1 bear rub was set in the study area. We used Akaike's Information Criterion corrected for small sample size (AIC_c) to rank our model sets (Akaike 1973, Hurvich and Tsai 1989). When the top model received

<0.90 of the model weight we model averaged the estimates of the model parameters across all models to account for model selection uncertainty (Burnham and Anderson 2002). We assessed the strength of evidence (SOE) for variables in the top model by calculating the likelihood that the beta coefficient was not 0 (i.e., evidence ratios for the beta coefficients):

$$\frac{\mathcal{L}(\widehat{\beta(i)})}{\mathcal{L}(0)} = \exp\left(\left\{\frac{\widehat{\beta(i)}}{SE(\widehat{\beta(i)})}\right\}^2\right),$$

where $\widehat{\beta(i)}$ is the beta coefficient for variable i and $SE(\widehat{\beta(i)})$ is the standard error of the beta coefficient for variable i (Burnham 2015).

We obtained permits under the Convention on International Trade in Endangered Species (Export Permits 12US86417A/9, 13US19950B/9, and 14US43944B/9) to export samples to Canada for analysis. Our research was authorized by the NMDGF (Taking Protected Wildlife for Scientific and or Education Purposes Permit 3504) and approved by the New Mexico State University Institutional Animal Care and Use Committee (Protocol number 2011-027).

RESULTS

Field Sampling and Genetic Analysis

We set 557 hair traps that were open for 57,010 trap days and we collected 3,825 hair samples. In addition, we identified and sampled 112 bear rubs, which yielded 258 hair samples over 7,007 trap days (Fig. 2; Figs. S1 and S2; Table S1). Sampling effort varied across study areas and was dependent on the number of detectors set, the length of a sampling occasion (4 weeks vs. 2 weeks), and accessibility due to weather and wildfire. The number of hair samples collected during an occasion increased over the course of the summer and decreased toward the conclusion of sampling with peak collection during June and July.

The mean observed heterozygosity was 0.73, 0.73, and 0.68 for the Sangre de Cristo, Sandia, and Sacramento

Mountains, respectively. Of the 4,083 total hair samples collected, we eliminated 26.08% because of insufficient genetic material, 1.49% because of heterospecific contamination, and 0.17% because the samples contained DNA from >1 individual. We generated a full 9-locus genotype from 49.56% of the 2,950 remaining hair samples from which we identified 726 (368 males: 358 females) individuals (Table S1). The number of individuals that were mismatched at 1 or 2 markers was low with only 3 observed 1-mismatched pairs and 8 observed 2-mismatched pairs across all samples. Genotyping success varied across study areas (44–61%), but overall, success rates were lower than the 75% success rate observed in similar studies (D. Paetkau, Wildlife Genetics International, personal communication). When we shortened the length of the sampling occasion from 4 weeks (NSC and SSC) to 2 weeks (Sandias, NSacs, and SSacs), the percentage of successful genotypes increased by only 4%.

Density Estimation

We detected the majority (61–85%) of individuals in each study area only once with a similar number of repeat detections for males and females (Table 1). The number of unique individuals detected during each occasion for the NSC, NSacs, and SSacs increased over the course of sampling, peaking mid-summer, and subsequently decreasing toward the end of summer; this pattern was similar to the number of hair samples collected per sampling occasion. The number of unique individuals detected increased each occasion for the Sandias and SSC. Mean maximum recapture distance for males in a single year of sampling ranged from 4.23 km to 12.46 km with a maximum distance of 52 km by 1 individual in the NSC. Mean maximum recapture distance for females in a single year of sampling ranged from 0.38 km to 4.59 km with a maximum distance of 47 km by 1 individual, also in the NSC (Table 1). Three individuals were detected in 2 study areas in successive years. We detected 2 males in the NSC in 2012 and then again in the SSC in 2013; we detected 1 female in the SSC in 2013 and 90 km away in the Sandia Mountains in 2014.

^a Detection probability at the activity center ($g0$) and the spatial scale over which $g0$ declines (σ) a function of elevation (elev), sex, time variation (t), or land cover type (cover); + = additive effect; constant = no variation. Density was held constant for all models listed.

^b Number of model parameters.

^c Model deviance = $-2(\log\text{-likelihood})$.

None of the top models included an animal by site learned response; however, the parameter structure of the top model with the addition of bk was the second ranked model in each study area except for the SSacs, where the behavioral model was third (Tables S2–S6). Although models that included bk reduced the deviance and appeared competitive in the model set, the deviances were nearly identical to the top model, so the extra parameter failed to substantially improve model fit. As a result, the support for bk models was likely a result of an identical model structure to the well-supported top models (Arnold 2010). Therefore, we removed all models that included bk from our model sets, and we report only on the reduced model sets hereafter.

There was little model selection uncertainty in each study area except in the SSacs with the top model garnering 50% of the total model weight (Table 2; Tables S7–S11). Detection probability ($g0$) was highest for the Sandias ($g0 = 0.029$ and 0.0017 for females and males, respectively), but overall, $g0$ was low across all study areas (Table 3). The land cover type or elevation at which the detector was deployed were helpful covariates in explaining heterogeneity in both $g0$ and σ for all

study areas except for the Sandias, which included sex as the only important explanatory variable (Table 2; Tables S7–S11). Models allowing $g0$ to vary over time were supported because $g0$ was low in early summer, increased as the summer progressed, and then decreased in late summer except in the SSC where $g0$ increased in each occasion. Detection probability increased as elevation increased in the SSC with σ exhibiting an inverse relationship. The SOE that the effect of elevation was not 0 was high for both $g0$ and σ (Table A1). In the Sandias, males showed a lower detection probability ($g0$) and higher movement rate (σ) than female black bears, and the SOE that the effect of sex on both parameters was not 0 was high (Table A1). The influence of land cover on $g0$ and σ across the NSC, NSacs, and SSacs was variable. The most consistent relationship was that $g0$ was lower and σ was higher within the piñon pine-juniper land cover type with aspen-conifer (NSC) and mixed conifer (NSacs and SSacs) land cover types as reference categories, respectively (Table A1). The SOE that the effect of land cover type was not 0 was high for all parameter-study area combinations except for σ in the NSacs. The effect of the

Table 3. Estimated abundance (\hat{N}) and density (\hat{D} ; bears/100 km²), coefficient of variation of the density estimate ($CV[\hat{D}]$), detection probability at the activity center ($g0$), spatial scale over which detection probability declines (σ ; km), and their 95% confidence intervals for American black bears in the northern (NSC) and southern (SSC) Sangre de Cristo, Sandia, and northern (NSacs) and southern (SSacs) Sacramento Mountains, New Mexico, USA, 2012–2014. We model averaged \hat{N} and \hat{D} for the SSC and SSacs using models with model weights > 0.00 and for the NSacs using the top-ranked model with density held constant and varying by sex.

^c Parameter estimate for male black bears.

ponderosa pine cover type on both g_0 and σ was negligible relative to aspen-conifer and mixed conifer (Table A1). In the NSC, spruce-fir and mixed conifer showed a negative relationship with g_0 and a positive relationship with σ relative to aspen-conifer (Table A1).

There was marginal support that density varied by sex in the NSacs ($\Delta AIC_c = 0.87$; $w_i = 0.61$ for the top model) and no support in all other study areas ($w_i \geq 0.75$ for the top models holding density constant; Table S12). Mean density estimates varied within and between mountain ranges (range = 16.6–25.3 bears/100 km²; Table 3) as did estimates of abundance given the different sizes of the study areas (range = 43.3–1,249.5 bears; Table 3).

DISCUSSION

By employing NGS with SECR models, we provided density estimates that will aid in setting harvest limits and serve as a benchmark for comparison with future research for multiple black bear populations in New Mexico. Our density estimates were similar to (SSacs) or higher (NSC, SSC, Sandias, and NSacs) than the previous estimates used by NMDGF to manage these populations (Costello et al. 2001). The differences in our estimates of density from those of Costello et al. (2001) are most likely due to differences in analytical techniques (the previous method did not account for imperfect detection) and we speculate due to potential changes in black bear population dynamics over the past decade. It should be noted, however, that the 95% confidence intervals surrounding our estimates typically encompassed those of Costello et al. (2001).

There is strong evidence that piñon pine-juniper land cover is associated with lower detection rates and increased movement rates, whereas an increase in elevation has the opposite association (Table A1). Like other ursid NGS studies, estimates of detection probability and movement rate varied over time and by sex in our study (Kendall et al. 2009, Sawaya et al. 2012, Stetz et al. 2014). For example, detection probabilities were lower and movement rates were higher during early and late summer, and males, in general, had higher movement rates than females. Detection probabilities also differed between the sexes in the Sandias (Table 3).

The importance of a temporal effect on g_0 and σ in the NSC, SSC, NSacs, and SSacs is likely a result of seasonal mating and foraging behaviors (Alt et al. 1980, Garshelis and Pelton 1981, Costello et al. 2003). During the breeding season, males increase movement rates as they traverse their home range searching for receptive females (Young and Ruff 1982, Costello 2008, Lewis and Rachlow 2011). In fall, bear home range size and distance between sequentially recorded movements increases as bears travel outside their core area to exploit the spatially and temporally variable oak mast (Ostfeld et al. 1996, Costello 2008), which is an important food source that was previously shown to be correlated with black bear reproductive output in New Mexico (Costello et al. 2003). These behavioral differences during mating season and hyperphagia would increase movement rates and enlarge home range size, thereby reducing g_0 while

increasing σ because of the compensatory relationship between the 2 parameters (Efford and Mowat 2014).

The influence of land cover and elevation on g_0 and σ is also likely a function of black bears responding to spatiotemporal changes in food abundance (Costello and Sage 1994, Mazur et al. 2013, McCall et al. 2013). During spring, or the pre-mast season, grasses, forbs, and ants dominate bear diets (den emergence to mid-Jul; Costello et al. 2001). Diets then shift toward soft mast species such as berries in the late summer and early fall (56% of scat volume, mid-Jul to mid-Sep), with fall (mid-Sep through Oct, den immergence) diets dominated by acorns (87% of scat volume) and supplemented with juniper berries (Costello et al. 2001, Guntley 2016). Mid-elevation land cover types (i.e., mixed conifer) are more likely to contain a higher abundance of grasses and forbs because of earlier snowmelt compared to higher elevations and higher levels of precipitation compared to lower elevations (Zlotin and Parmenter 2008). As snow melts, the availability of grasses and forbs increases with soft mast ripening with the arrival of summer rains. Once hard mast species begin to ripen in late August (Zlotin and Parmenter 2008), black bears shift their attention toward land cover types containing those species (Costello and Sage 1994, Onorato et al. 2003). Thus, the availability of grasses and soft mast at mid- to high- elevations and the scarcity of food in the low elevation piñon pine-juniper cover type during summer (Zlotin and Parmenter 2008) may explain the negative relationship with g_0 and the positive relationship with σ for piñon pine-juniper and low elevations for all study areas except the Sandias (Table A1). Black bears are also predators of elk calves in portions of New Mexico and they may move toward calving grounds in spring, which are commonly found at higher elevations (Quintana 2016).

Half of our samples that met our quality threshold failed to produce a reliable genotype, which reduced the number of unique individuals identified and the number of recaptures. The lack of data also likely contributed to the low detection probabilities and affected our ability to estimate σ precisely (Efford et al. 2004, Sollmann et al. 2012, Sun et al. 2014). However, simulation has shown that SECR models provide relatively robust estimates of density under data dilution scenarios (Mollet et al. 2015). The relatively more precise NSC density estimate, despite a low g_0 , may be a result of a greater number of unique individuals and recaptures, which provided sufficient data for the model to predict unobserved movement distances (Table 1; Sollmann et al. 2012, Sun et al. 2014). Whereas g_0 was the highest for the Sandias, the density estimate was the least precise. This relatively low level of precision was most likely caused by the few individuals detected ($n = 18$) and a low number of spatial recaptures, which may have contributed to poor estimates of σ and an inability to predict unobserved movement distances (Sollmann et al. 2012). The low sample size and few recaptures is further evident in the simple structure of the top models and the high coefficient of variation for the estimate of density (Tables 2 and 3).

We suspect that for all study areas, intense ultraviolet (UV) radiation coupled with extended sampling intervals were the

main factors explaining the poor genotyping success we observed (Stetz et al. 2015). Ultraviolet radiation causes DNA degradation by forming dimers between adjacent pyrimidine bases, instead of those bases binding with their cross-strand partners, which prevents the DNA polymerase from progressing past the dimer and results in an incomplete genotype (Jagger 1985). Factors influencing UV levels include cloud cover, elevation, latitude, shade, length of exposure, season, ozone depletion, and atmospheric turbidity (Piazena 1996, Stetz et al. 2015). For example, UV radiation increases with decreasing cloud cover, increases with elevation (9–11% per 1,000 m), and increases with decreasing latitude (Blumthaler et al. 1997). The UV radiation levels across much of New Mexico are higher than across most of the United States and are higher than other regions where NGS methods have been used to estimate bear abundance and density (Fig. 3; National Oceanic and Atmospheric Administration [NOAA] 2012). Further, we would expect UV radiation levels to be 1–26% higher in our study areas compared to those for Albuquerque, New Mexico, where the NOAA (2012) UV measurement was taken, because our study areas were at equal or higher elevations. Reducing the sampling interval should have increased genotyping success; however, when we reduced our sampling interval from 4 to 2 weeks (which is a common period used by similar NGS studies in the western United States), we observed only marginal improvement in genotyping success (4%).

In the SSC, we also lost hair samples because of 2 forest fires, the Tres Lagunas (4,135 ha) and the Jaroso (4,511 ha). These fires affected 450 km² (12.7%) of the trapping grid and prevented us from accessing and checking hair traps located near the fire, primarily during the second and third sampling occasions (3–13% of total hair traps; Fig. S3). Moreover, many of the fire-affected traps were in an area where we expected higher bear abundance. Anecdotally, these hair traps consistently yielded more hair samples post-fire than hair traps located in some areas that were unaffected by the fires. The limited access also prevented us from identifying more bear rubs across the SSC, restricting our use of multiple sampling methods and hindering our ability to minimize the impacts of capture heterogeneity present with any one survey method (Boulanger et al. 2008).

Despite UV radiation and sampling difficulties, our density estimates had levels of precision comparable to those obtained in other black bear studies conducted across the United States that used NGS and a SECR estimator (Table 4). The level of precision we achieved may have been a consequence of the large extent of our study areas, which may have allowed us to detect a large proportion of the population within each mountain range even though we failed to amplify approximately half of our samples. Our density estimates fell within the middle range of NGS and SECR-based black bear density studies (Table 4). Black bear density was highest on the east coast in pocosin, which is characterized by high food production and cover, low human disturbance, and agricultural food resources mixed throughout (Tredick and Vaughan 2009, Drewry et al. 2013). Eastern populations inhabiting pine plantations were at densities comparable to

New Mexico populations likely because pine plantations had limited food, insufficient cover, and fewer agricultural food resources as compared to pocosin (Tredick and Vaughan 2009, Drewry et al. 2013, Hooker et al. 2015). Locally, our estimates are similar to or lower than those in southern Colorado, USA, and similar to or higher than those in northern Colorado (Table 4); however, estimates for southern Colorado fluctuated substantially within each study area and over multiple years. Populations with densities lower than ours were expanding their range (Sun et al. 2017), recolonizing (Wilton et al. 2014), residing in habitat with low food resources (Drewry et al. 2013), or were sympatric with grizzly bears (*Ursus arctos*; Stetz et al. 2014).

We provided updated density estimates for an important game species in New Mexico. Our estimates add to a growing number of studies that have used NGS coupled with SECR models to estimate the density of black bear populations across the United States. Our data suggest that the detection probability of black bears is likely influenced by the abundance and distribution of food resources on the landscape, which in turn, may be influenced by land cover type and elevation. Furthermore, UV radiation levels in New Mexico appear to be higher than elsewhere in the contiguous United States and are also most likely responsible for our low rate of genotyping success, a rate comparable to those in the high Arctic of North America (Dumond et al. 2015).

MANAGEMENT IMPLICATIONS

Our estimates of density will assist the New Mexico Department of Game and Fish in setting sustainable harvest limits for multiple populations of black bears in New Mexico. We suggest that researchers using hair samples to monitor wildlife populations incorporate a pilot study to evaluate the effects of UV degradation, among other factors, on genotyping success. To help reduce UV exposure, researchers could set detectors in more shaded areas (e.g., north facing slopes), set fewer detectors so that they can be checked more frequently, or increase the number of personnel used to check detectors. We believe more personnel is preferable to fewer detectors because it allows for a larger study area, a denser trapping array, or alternative trapping configurations to be sampled. A larger study area will help mitigate the effects that seasonal movement patterns can have on parameter estimates, particularly in areas with highly variable food resources, and provide density estimates at the spatial scale at which many agencies make management decisions.

ACKNOWLEDGMENTS

Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the United States Government. We thank our technicians and volunteers for their dedication: S. S. Allen, C. J. Barela, D. S. Carter, K. A. Cobb, W. M. Dooling, J. D. Larson, W. J. Lubenau, T. L. Melham, C. J. Morrow, A. A. Orlando, S. R. Stroik, T. T. Turnbull, R. C. Wilbur, L. A. Ahlm, N. M. Carrier, A. C. Cook, L. C. Dhaseleer, G. J. Holm, S. J. Holms, S. E. Leonard, P. R. McGrew,

R. D. Welch, and the Sandia Mountain Bear Collaborative. We thank the private landowners who provided access to their property: Angel Fire Resort, Atmore Express Ranch, Buena Vista Ranch, C.S. Cattle Company, Chase Ranch, Dawson Ranch, Endless Blue Resort, Flying Horse Ranch, Fort Union Ranch, Gary Bates, G-F Ranch, I-X Ranch, Jeannie Blattmon, National Rifle Association – Whittington Center, Ojo Feliz Ranch, Perry Ranch Inc., Philmont Scout Ranch, Rio Costilla Cooperative Livestock Association, Sandia Pueblo Bobcat Ranch, Torres Ranch, Wheaton Creek Ranch, Ute Creek Ranch, UU Bar Express Ranch, Vista del Valle Ranch, and Vermejo Park Ranch. We appreciate the support from numerous NMDGF biologists and conservation officers: C. J. Coburn, E. J. Goldstein, K. T. Jackson, T. J. Jackson, J. M. Kline, S. G. Liley, C. Neary, R. J. McBee, E. Nelson, M. A. Peralta, S. M. Murphy, R. N. Walker, L. D. Vanlandingham, and F. S. Winslow. We also thank L. O. Cordova, F. E. Cortez, S. C. Naegel, E. I. Nelson, M. V. Orr, and T. A. Rawlinson from the United States Forest Service (USFS) for their logistical help and the numerous federal and state agencies and private entities that provided invaluable in-kind and logistical support: Kit Carson Electric Cooperative, Mountain View Regional Medical Center, Caviness Beef Packers, Mora-San Miguel Electric Cooperative, NMDGF regional offices, Otero County Electric Cooperative, United States Bureau of Land Management, and the USFS (i.e., Carson, Lincoln, and Santa Fe National Forest). Our project would not have been successful without the technical expertise provided by J. B. Stetz and W. Simoneau, the computation resources provided by D. V. Toups Dugas and C. M. Henderson with the New Mexico State University Information and Communication Technologies program, the invaluable wilderness knowledge passed on by T. P. Howes and H. H. Ley, and the hospitality provided by the Smith family, R. A. Smith and staff, and many others along the way. Comments by T. A. Graves, S. M. Murphy, M. A. Sawaya, T. F. Wright, and 2 anonymous reviewers helped improve this manuscript. The NMDGF, the New Mexico State University Department of Fish, Wildlife and Conservation Ecology, the New Mexico State University Department of Biology, Vermejo Park Ranch, and T & E Inc. provided funding.

APPENDIX A. Relationship and effect of covariates on spatially explicit capture–recapture model parameters.

Table A1. The beta coefficient (Beta), standard error (SE), and lower (LCL) and upper (UCL) 95% confidence intervals for covariate variables from the top ranked spatially explicit capture–recapture model for American black bears in the northern (NSC) and southern (SSC) Sangre de Cristo, Sandia, and northern (NSacs) and southern (SSacs) Sacramento Mountains, New Mexico, USA, 2012–2014. Included is the strength of evidence (SOE) of the likelihood that the beta coefficient is not 0 where larger values indicate a greater SOE that the effect of the variable is not 0. The reference categories for land cover type were aspen-conifer (NSC) and mixed-conifer (NSacs and SSacs), and the reference category for sex (Sandias) was female. Model parameters include detection probability at the activity center (g_0) and the spatial scale over which g_0 declines (σ).

Variable	Parameter	Study area	Beta	SE	LCL	UCL	SOE

Research Summary 2019–2021

Estimating Black Bear Abundance Using Spatial Capture-Recapture in Bear Management Zones 1 and 10

Introduction:

Management of black bear hunting in New Mexico is predicated on regulation through a Bear Management Zone (BMZ) system, wherein a BMZ is a collection of Game Management Units (GMUs) across which there are similar habitat, landscape connectivity, and high likelihood of strong, local population dynamics occurring. These BMZs are not isolated populations, as ear-tag and GPS collar data over the years have shown bears moving large distances across the state and beyond. However, the sky-island effect that creates large stretches of non-preferred habitat between core areas of bear habitat in New Mexico (Atwood et al. 2011), as well as social considerations that drive hunting pressure and human-bear interactions, necessitate management at this local-population level, while recognizing the existence of metapopulation dynamics across the state.

Bear hunting is managed through this BMZ system by setting zone-specific harvest limits that restrict the number of bears that can be taken in a given zone. Currently, setting bear harvest limits relies on density estimates from two study areas and traditional capture-recapture methods using live capture and radio-telemetry tracking (Costello et al. 2001) and three mountain ranges where modern non-invasive genetic sampling (NGS) was used (Gould et al. 2018). Those density estimates were then applied across the amount of primary bear habitat in a zone as defined by a habitat suitability model developed in 2015. Although bears use secondary and edge habitat, these habitats were not included in density estimation resulting in conservative estimates. Population estimation through this extrapolation of density estimates to bear habitat is used for the zones where these studies occurred, as well as for other zones according to similarities in habitat and geography.

From that zone-specific population estimate, hunting is managed for a sustainable harvest by allocating only 8–12% of the population estimate as the total allowable harvest for that zone (Miller 1990). To further ensure sustainable populations, only 30% of that 8–12% total harvest limit can be female bears without cubs. A zone closes when the harvest reaches either the total harvest limit or the female sub-limit, or if neither limit is reached then zones close at the end date of the season. Hunters are required by law to have their harvested bear pelt-tagged with a Department employee or law enforcement officer within five days of harvest, allowing the Department to how many bears have been harvested and close the zone accordingly.

The study by Gould et al. (2018) was the first implementation of modern NGS (via ‘hair snares’) to monitor black bear populations in New Mexico. The use of hair snares (barbed wire corrals that pull hair from bears as they pass across the wires to access bait) allows for large geographic areas to be sampled and a high volume of captures with compared with traditional capture-recapture methods (Woods et al. 1999). Used in conjunction with spatial-recapture (SCR) models, which can accommodate large sampling areas and explicitly link estimation to the space in which animals occurred, we can generate estimates of population size at a scale meaningful to management with no need for extrapolation. Of those zones not covered by Gould et al. (2018) we chose BMZs 1 and 10 for implementation of this NGS and SCR modelling approach.

Bear Management Zones 1 and 10 consistently have had high harvest over the past 12 years, reaching the total or female harvest limit most years. Both zones have also had recent

landscape altering wildfires (2011's Las Conchas fire and preceding fires in BMZ1; 2012's Whitewater-Baldy fire in BMZ 10), which may have had both negative effects (short-term displacement during fires) and positive effects (eg. beneficial seral stage of vegetation communities with abundant mast and forage). Obtaining contemporary estimates in these zones, using updated analytical techniques, will provide the best available information for sustainable management of black bear populations in those zones.

Methods:

Study Area

The BMZ 1 study area (14,043 km²) included GMUs 4, 5A/B, 6A/B/C, 51A/B, and 52. These GMUs are a contiguous area of similar bear habitats in the Jemez Mountains and southern San Juan mountains, as well as surrounding foothill and lowland habitats, that are representative of various habitat types under the 'Southern Rockies' Ecoregion III level habitat classification (Griffith et al. 2006). This study area did not include GMU 7, which is also part of BMZ 1 and has contiguous, suitable bear habitat with the study area. However, habitat in GMU 7 transitions into San Juan/Chaco tablelands habitats that becomes more arid and sparsely forested as you head west from the study area. Given the difference in habitat type and logistical constraints for sampling that additional area, we did not include GMU 7 in the study area.

The BMZ 10 study area included GMUs 15, 16A/B/C/D/E, 17, 21A/B, 22, 23, and 24. These GMUs are a contiguous area of similar bear habitats in the Greater Gila region that are representative of various habitat types under the Arizona/New Mexico Mountains Ecoregion level III habitat classification (Griffith et al. 2006). This study area did not include GMUs 12 and 13, which have contiguous suitable bear habitat with the study area; nor did the study area include GMUs 18, 20, 26, or 27, which have sky-islands of suitable bear habitat separated from the study area by large expanses of non-preferred lowland habitat. These GMUs were not included because of the logistical constraints of sampling such a large area.

We established hair snare sites within all habitat types as identified in the Department's 2015 habitat model for black bear (Figures 1 and 2). This allows for area-wide estimation of population size, in recognition that bears utilize multiple habitat types, movement occurs between patches of primary habitat, habitat may change year to year, and to model the population with as direct an estimate as possible of the management area and minimize or eliminate the need to extrapolate to a habitat model.

Field Sampling

Simulations indicated that clusters of detectors with 1.6-km spacing between detectors, 11.2-km spacing between clusters, and sampling for 8 occasions would produce precise and unbiased density and abundance estimates from spatial capture-recapture models. We deployed hair snares in grids of 6–12 sites, with spacing of 1.2–2.4 km (2019 avg. = 1.63 km; 2020 and 2021 av. = 1.48 km) between sites to adjust for access and the effect of topography and landscape ruggedness. Grids were spaced roughly 11.2 km apart. We revisited sites every 7–10 days for a total of 8 occasions spanning early June to mid-August. Hair snares were set with two strands of barbed wire wrapped around ≥ 3 trees, with one strand at 35 cm high and another at 65 cm high (Woods et al. 1999). Bait (pastries) were placed at the center of the hair snare, and a scent lure (cherry and anise oil) was applied to the site and surrounding area.

Samples were collected from the barbed wire strands, off of trees which the barbed wire was attached to, and off the ground if the bear rubbed against objects on the ground within the hair snare. A sample consisted of all the hair at a single barb, or hair from up to three adjacent

barbs (along the same wire or vertically adjacent on each strand) if the hair was consistent in appearance. Hair was deposited in a paper coin envelope, and the barbs from which the hair was collected were sterilized with a lighter.

Genetic Analysis

We did not analyze samples if they contained zero guard hair roots and <5 underfur hairs, or if they were visually recognized as nontarget species. Following the initial screening, we purified DNA from the remaining samples using QIAGEN DNeasy Blood and Tissue kits, ran samples through a single-locus prescreening to identify samples that were degraded, unsuitable, or from nontarget species. Samples that passed the prescreen were analyzed at 9 microsatellite loci (including the ZFX/ZFY marker used for the pre-screen) used previously for black bear in New Mexico (G1D, G10B, G10H, G10J, G10L, G10M, G10U, MU59; Gould et al. 2018). For any sample with mismatch pairs at one or two loci, we amplified those samples at another three loci (CXX20, CXX110, and G10X) to determine whether the mismatches were due to genotyping error or if the samples were from different individuals (Kendall et al. 2009). We then assigned an individual identifier for each unique 9-locus genotype (or 12 locus genotypes for those that had one or two loci with mismatches between replications). Genotyping of all hair and tissue samples, error-checking, and PCA analysis of genotypes was conducted by Wildlife Genetics International in Nelson, British Columbia, Canada (WGI; Paetkau 2003).

Density Estimation

We used spatial capture recapture (SCR) models (Efford 2004, Borchers and Efford 2008) from the secr package (v. 4.5.3, Efford 2022) in program R to estimate population size (\hat{N}), baseline detection probability at an individual's activity center (g_0), and the movement coefficient for decay in detection as distance from an activity center increases (σ). We modeled density as uniform across space with a homogenous Poisson point process, and an observation model using the half normal detection function. We defined the 'state space' (a mathematical representation of the effective sampling area across which animals can be detected) by creating a polygon from the 2015 bear habitat model using primary, secondary and edge habitats for BMZ 1, and only primary and secondary habitats for BMZ 10. We then buffered those polygons (5 km for BMZ 1, and 4 km for BMZ 10) by distances suggested by the suggest.buffer function in the secr package, which allows for the models to account for bears that could occur at the edge of the state space (Royle et al. 2014).

We evaluated a set of models that included a trap-specific behavioral response (bk) on g_0 because the sites were baited, and evaluated for sex-specific predictors for estimates of g_0 and σ . Estimates were made for each study area separately. We pooled data for BMZ 10 across 2020 and 2021 to get a single population estimate because geographically distinct portions of the study area were sampled each year. We evaluated models using Akaike's Information Criterion corrected for small sample size (AIC_c), and used model averaging if AIC_c weight was less than 0.90 for the top model.

Results

Field Sampling and Genetic Analysis

In BMZ 1 during 2019, we collected 1,097 samples from 179 sites over eight 7–10 day sessions. Of those samples, 714 (65%) were visually identified as bear hair or had enough material for DNA analysis, and of those samples 482 (68%) were genotyped to an individual identification for a total of 94 bears (49F:45M) Those 482 successfully identified samples represented 191 unique detections of individuals across sites and occasions (Table 1).

In BMZ 10, we collected a total of 1,706 samples (1,012 in 2020; 694 in 2021) from 349 sites (249 in 2020; 110 in 2021) over eight 7–10 day sessions. Of the 1,012 samples from 2020, 895 (88%) were visually identified as bear hair or had enough material for DNA analysis, and of those samples 725 (81%) were genotyped to an individual identification for a total of 152 bears (74F:78M). Those 725 successfully identified samples represented 311 unique detections of individuals across sites and occasions (Table 1). Of the 694 samples from 2021, 657 (94%) were visually identified as bear hair or had enough material for DNA analysis, and of those samples 493 (75%) were genotyped to an individual identification for a total of 118 bears (63F:55M). Those 493 successfully identified samples represented 244 unique detections of individuals across sites and occasions (Table 1). One male bear was detected both years, once in 2020 and three times in 2021 approximately 16 and 35 km away.

Through our error-checking process that compared samples with mismatches, we found two samples in 2019 with a mismatch at two markers, and those were amplified at the additional three loci to distinguish that these samples came from different individuals. Mismatches at two loci were found for 30 samples in 2020, and amplification at the additional three loci revealed that these were not due to genotyping error and were due to the samples coming from different bears. In 2021, mismatches at two loci were found for 29 genotypes, and amplification at the three additional loci revealed differences at those loci as well confirming that the genotypes were from different bears. A genotype-based PCA analysis to assess potential outliers revealed slight overlap between BMZ 1 and BMZ 10, but a stronger pattern of genetic differentiation between the zones (Figure 3).

Density Estimation

The number of re-detections of individuals at a single site across different occasions, or at multiple sites, represented a significant portion of the detections at each study area (Table 1). The average distance moved between sites was 2,402 m in BMZ 1 and 2,964 in BMZ 10, with a maximum distance moved of 7,725 m in BMZ 1 and 21,904 in BMZ 10.

The top two models (>0.9 AIC_c weight) for BMZ 1 included both behavioral and sex effect on g_0 , and differed in including a sex effect on sigma (Table 2). Similarly, the top model for BMZ 10 (AIC_c weight = 1) included behavioral and sex effects on g_0 , and a sex effect on sigma (Table 2). Model estimates of population size (\hat{N}) for the given study area were 1,574 (95% CI = 1,050 – 2,358) in the BMZ 1 study area, and 2,192 (95% CI = 1,791 – 2,698) in the BMZ 10 study area (Table 3). Estimates of g_0 and sigma were similar across both study areas (Table 3).

Discussion

Our estimates of population size are similar to previous estimates for BMZ 1 (17 bears per 100 km² of primary habitat), and higher than previous estimates for BMZ 10 (9 bears per 100 km² of primary habitat, Costello et al. 2001). In BMZ 10, converting the population estimate to a density per 100km² of primary habitat to compare to the method previously used to estimate population size, returns a density of 15.9 bears per 100km² of primary habitat. That estimate is similar to densities found for other New Mexico mountain ranges (Gould et al 2018) and to a similar conversion of our results for BMZ 1 (16.9 bears/100 km² of primary habitat). This observed higher density is more reasonable given the understanding that the Gila region contains highly productive bear habitat, comparable to other mountain ranges in New Mexico. The previous estimate is much lower than densities that have been found in more contemporary studies conducted in similar New Mexico habitat using NGS and SCR.

The goal of this study was to estimate population size across the entire area of a BMZ, but even with the easing of logistical constraints when using NGS this broad coverage was still not entirely possible for these studies. These population estimates for the given study areas are for a significant portion of each zone, however there were still GMUs with bear habitat that were not covered and for which extrapolation will be necessary to get a zone-wide population estimate. The contemporary estimates from our studies will provide a robust baseline from which to make those extrapolations to these neighboring GMUs, which are contiguous with habitat in our study areas and in close proximity to them. The Department will make these extrapolations at the most conservative levels informed by the confidence intervals we observed.

These studies were conducted in years of unique environmental conditions, including an ongoing, historic drought. Both of these study areas share a similar post-fire dynamic (similar large burns in the early 2010s), and moderate wildfires burned in BMZ 10 while we conducted sampling (the Cub, Good, and Tadpole fires in 2020; the Johnson fire in 2021). The role of fire on landscapes in the Southwest is complex and changing, however it should be noted that low to moderate intensity fires are a natural stochastic event for these ecosystems and the species that live here have adapted to persist in the face of that change. The population estimates we found through these studies are encouraging in illustrating the ability for these black bear populations to persist through the immediate dangers of a wildfire, and thrive on the post-fire landscape.

We achieved higher success rates for genotyping than previous efforts in New Mexico (Gould et al. 2018), which we attribute to the decreased time between sampling occasions (7–10 in our study; 14–28 days in previous study) which subsequently decreased exposure time to environmental conditions. The higher genotyping success rates we observed resulted in a greater number of observations, and in combination with sampling across multiple habitat classifications we had a robust data set for modeling over such a large area.

The Department plans to continue implementing this methodology in BMZs throughout the state to provide contemporary estimates in zones not previously studied and in zones where significant habitat changes may occur. Future work will focus on evaluating models for the effect of habitat variation on density, analyzing data from trail cameras at hair snare sites to compare camera detections to NGS captures, looking at metapopulation dynamics and population genetics to investigate further geneflow between zones, and genotyping harvested bears from zones where we've conducted our studies to compare with animals detected through our research efforts. In conjunction with these point estimates of population size generated by these studies, the Department is also developing an Integrated Population Model (IPM) approach for monitoring population dynamics in each zone. These IPMs will incorporate data from a variety of sources, including: over 20 years of age, sex, and hunter effort harvest data, population estimates from our SCR studies, and survival and other population demographic information collected through the Department's or our collaborator's research efforts. All of these data sources will go into these IPMs to monitor abundance and other demographics annually.

Table 3. Estimated abundance (\hat{N}) and 95% confidence interval, detection probability at an activity center (g0), and movement coefficient for decay in detection over space (σ [km]) for the top ranked model. Density (\hat{D}) is reported here as the number of bears per 100 km² of primary habitat within the study area as identified in the Department’s 2015 habitat model for comparison to previous estimation technique.

	\hat{N} (95% CI)	g0	σ	\hat{D} (95% CI)
BMZ 1	1,574 (1,050 – 2,358)	0.08	1.80	16.9 (11.2 – 25.3)
BMZ 10	2,192 (1,791 – 2,698)	0.07	1.95	15.9 (12.4 – 18.6)

Update to Bear Habitat Model for the 2016-2020 Rule

Introduction

Black bears are cryptic, mainly solitary animals that prefer areas with dense cover, and therefore cannot be directly counted through aerial or ground surveys. Density estimates are derived through collecting field data on individually marked animals and applying population reconstruction or mark-recapture analyses to the data. Habitat models estimate quantity and location of bear habitat around the state, and bear density estimates generated for mountain ranges or specific habitat types can be extrapolated to similar areas to derive a statewide population estimate. In this paper, we describe the process used to update the original habitat model using the most current technology available.

The original habitat model for black bear population estimation in New Mexico was generated as part of the 9 year Black Bear Ecology Study (hereafter 2001 study, Costello et al. 2001) conducted 1992–2000 (Fig. 1). This habitat model utilized the New Mexico Gap Analysis Program (NM GAP) land cover classification which was designed to predict species distribution based on habitat type. The NM GAP model was used, in conjunction with information gathered from 316 radio-collared bears across 2 study areas and mast production potential by habitat type, to predict primary, secondary, and edge habitat classifications across New Mexico. NM GAP had several data limitations (Costello et al. 2001, p. 109), and the habitat model was intended to be updated as new information became available (Costello et al. 2001, p. 111). Advances in technology such as more detailed and accurate land cover classifications (the Landscape Fire and Resource Management Planning Tools (LANDFIRE) land cover classification), ability to identify individual animals through genetic techniques (Boerson et al. 2003, Lukacs and Burnham 2005), improved spatial data, and more accurate statistical methods provide an opportunity to develop more accurate population estimates.

Improved land cover classification and models are available through the Southwest Regional GAP and the more recently developed LANDFIRE datasets, which improve upon the shortcomings of the NM GAP. The habitat model from the 2001 study depended on the NM GAP dataset because it was the only comprehensive, statewide dataset available at the time. It posed substantial limitations (Costello et al. 2001, p. 109) due to poor classification accuracy (especially for habitat types important to bears) and inability to separate habitat type from cover density. As an example, the NM GAP model accurately predicted Rocky Mountain/Great Basin Open and Closed Conifer habitat types on average 28% and 15%, respectively (Thompson et al. 1996). In comparison, LANDFIRE separated these into multiple vegetation classifications, each with 10 canopy closure classifications, and the resulting model accurately predicted the analogous habitat types approximately 88% and 79% of the time, respectively (Stehman 2012).

Substantial improvements in habitat classification accuracy and the ability to separate habitat type from cover density were important developments in the new LANDFIRE datasets. The number of habitat classifications increased from 42 in NM GAP (Appendix A) to more than 150

in LANDFIRE allowing for fine-scale classification in areas where there were previously few classification options. This allows for greater discrimination across similar habitat types and improved classification accuracies. As an example, the single Rocky Mountain Upper Montane Conifer habitat type from the NM GAP can be compared to 9 habitat types within the LANDFIRE dataset including 6 mixed conifer classifications, 2 riparian classifications, and 1 aspen classification. Cover type classifications have become more standardized, allowing for consistent and repeatable land cover classifications, and a greater depth of information for comparison across years. The updated habitat model (Fig. 2) is based on LANDFIRE data for 2008, 2010, and 2012, which improved the robustness of the final model as it does not depend on a single year of data.

Separating canopy closure from vegetation classification data is another improvement in the LANDFIRE database. For example, NM GAP separates the Rocky Mountain/Great Basin Open and Closed Conifer Woodland classifications based on vegetation type and canopy density within a single dataset. By comparison, LANDFIRE separates vegetation classification and canopy closure into 2 datasets which provides improved discrimination in vegetation classification while maintaining the ability to differentiate by canopy closure. The aforementioned NM GAP classifications are separated in LANDFIRE into at least 4 vegetation classifications and canopy closure classifications in 10% increments.

Advances in genetic laboratory techniques have resulted in more sophisticated bear density estimation methods. The 2001 study captured as many animals as possible and used population reconstruction methods to estimate densities. It was assumed not all resident bears were captured; therefore, population estimates were considered minimum, not average, population sizes (Costello et al. 2001, p. 88). In contrast, hair-snare studies can employ spatial capture-recapture statistics which produce average population estimates and associated confidence intervals, as opposed to the point estimate produced by population reconstruction. Recent developments in statistical models have alleviated some of the uncertainties in classic capture-recapture population models and should provide more accurate estimates (Gardiner et al. 2010). Genetic hair snare studies are currently being employed around New Mexico to estimate bear densities across several mountain ranges, and the results are being used in conjunction with the updated habitat model to provide more accurate bear population estimates.

The advent and increased use of GPS radio-collars has provided insight into movement rates and capabilities of bears. Bears travel longer distances than previously believed, increasing the maximum distance between viable population centers (Liley and Walker 2015). Increased movement capacity, especially by breeding males, also provides more flexibility in the patch size and distance-based metrics of model assumptions because a population can remain sustainable with fewer individuals as long as sufficient breeding is maintained. In addition, larger patches separated by a long distance are often connected through linear patches of habitat (e.g., mesa edges and riparian canyons) that are not typically considered primary bear habitat. These linear

patches act as stepping stones for longer distance movements and subsequently improve connectivity across the landscape.

Methods

As a means of incorporating up-to-date and comprehensive landcover data, we employed LANDFIRE datasets to update the bear habitat model. These data result from the partnership between the U.S. Forest Service and Department of the Interior to provide consistent nationwide landcover mapping for fire management and general resource use, and are the most accurate and updated datasets available. These data are based on 30-m Landsat satellite imagery and have a reported accuracy of 0–100% depending on landcover type with forest and woodland landcover types having a user accuracy of 87.8% in the Southwest super zone (Bobbe et al. 2006). Datasets are updated every 2 years, and we acquired the 3 most recent vegetation type datasets (i.e., 2008, 2010, and 2012) from the LANDFIRE website (<http://www.landfire.gov/>) for this analysis.

We determined suitability of available cover types based on food availability and their use by bears. Cover types and their corresponding values as bear habitat were modified from the 2008 to the 2010 model because cover types were further refined (Appendix B and C). We omitted cover types with <10 cells throughout the original LANDFIRE image if they were of questionable importance to bears. Cover types were classified either as bear habitat or non-bear habitat, and did not specify primary and secondary classifications as in Costello et al. (2001); instead we depended on the selection criteria to determine the primary, secondary, and edge designations. We used the Extract by Attributes tool within the Spatial Analyst extension of ArcGIS to subset the LANDFIRE datasets based on the appropriate cover type value (Appendix B and C). Extracted values were reclassified into a single value and the 3 datasets were added together, keeping only the areas where all 3 datasets agreed.

We used the Aggregate tool in Spatial Analyst to sum across the final dataset by a factor of 7 to generate an output in 210-m-sided (0.0441 km^2) blocks. We selected 7 as the best aggregate factor from a test run across aggregate factors 2–10 based on knowledge of bear use across the state while balancing the smoothing effects of the aggregation. This also accommodated errors within the LANDFIRE dataset by eliminating small areas. We visually inspected the distribution of aggregated values and assigned a cutoff of 25% as an acceptable breakpoint between “edge” and “primary” designations. Areas that fell below the break point were considered edge habitat and were not included in the final model areal calculations. To allow for areal calculations and patch size selection, we converted the model raster to a polygon feature class without simplification.

We created a filter from LANDFIRE 2012 existing vegetation cover data by creating a raster with human-dominated cover types, barren areas, and cover classes <20%. We only used the 2012 dataset as there are concerns about the validity of canopy cover data in earlier LANDFIRE datasets (Scott 2008). We reclassified the appropriate cover classes to the same value (Appendix D), aggregated them to a 210-m cell, and kept the top 75% of cells (to match the habitat

classification aggregation). We converted this to a polygon and filtered the model. We converted multipart features to single-part features prior to the selection process, and updated the area calculation. The same filter was used to further discriminate bear habitat in GMU's 10, 12, and 13 except we included cover classes <30%. The GMU 10, 12, and 13 areas were replaced with the 30% model outputs in the final model area calculations.

The Select Layer by Location and Select Layer by Attributes tools were used to set distance-based search criteria and patch size requirements, as follows:

- All features $>200 \text{ km}^2$ were selected from the initial data set as main patches based on minimum habitat size needed to support a minimum viable population of 45–50 individuals. Use of a patch size smaller than the 300 km^2 used by Costello et al. (2001) is based on more accurate bear density estimates produced by the current bear density study, and documentation of larger distances moved as provided by GPS radio-collars. Inclusion of parcels $200\text{--}300 \text{ km}^2$ defined the Dry Cimarron area in GMU 58 and the Los Pinos Mountains in GMU 18 as bear habitat, both of which are known to sustain sizable bear populations. The Peloncillo Mountains, known to support a bear population, fell just below the 200 km^2 minimum, but were included due to proximity of large patches of bear habitat in Arizona.
- We varied both distance to and minimum patch size within biologically reasonable values, with minimal impact on the resulting habitat model. We selected all features within 30 km of main patches that were $>25 \text{ km}^2$ because they included key areas with known populations of bears including the Oscura Mountains in GMU 19, Sierra Grande in GMU 56, and the complex around Mesa Rica in GMU 42. These values are greater than those used in Costello et al. (2001; all features within 15 km of main patches that were $>20 \text{ km}^2$) because data showing that bears move larger distances means that they can move between patches spaced more widely apart, and higher bear densities on the landscape mean that smaller patches can support the 1-2 bears necessary to be considered bear habitat.
- All selected parcels included a 2 km buffer because black bears consistently use areas within 2 km of primary bear habitat.
- All holes smaller than 2 km^2 were closed with the Eliminate Polygon Part tool as a means of matching the 2 km “buffer” in the previous step and following a methodology similar to Costello et al. (2001).

We used the Intersect tool to combine the final selection output with the Game Management Unit shapefile. Total area (km^2) for each GMU was generated using the Summary Statistics tool. Areas that did not meet the selection criteria as secondary habitat and areas that fell below the 25% aggregation were classified as edge habitat. We did not include secondary or edge habitats in area calculations, but have included them in the map as areas of potential use by bears (Fig. 1, Table 1). The Python code for the classification and selection process is included in Appendix E.

We verified bear mortality locations from 1994–2014 through spatial location and agreement with the reported GMU. There were 9,852 mortalities in the database, of which 197 (2.0%) had

the UTM zone interpolated from the GMU and Easting, 91 (0.9%) were removed for falling outside the geographic bounds of NM, 1,039 (10.8%) were removed due to a disparity between the GMU and the UTM coordinate, and 643 (6.7%) were removed due to lacking or incorrect spatial information. We overlaid the 7,809 spatially-verified mortalities on the new habitat model as a check of model validity (Table 2). Hunter harvest locations (n = 6,863) occurred in primary habitat more often than depredation (n = 676), road kill (n = 239), and other (n = 31) locations. The new model contained 83% of sport-harvest mortalities within primary bear habitat.

We could not directly compare our model validity results with those of the 2001 study (p. 100) due to differences in methodologies. Specifically, our verified sport-harvest location data set was from 1994-2014, as opposed to the 1990-1999 data set used in the 2001 study. Next, although both studies verified mortality locations using some of the same standards, there was not enough detail in the 2001 study report to know if the standards were identical. Differences in standards for which records to include and how modifications were made could lead to very different results. Finally, Costello et al. (2001) did not verify the accuracy of the habitat model. Rather, she created a generalized distribution map identifying major regions of bear habitat (p. 95; e.g. Sangre de Cristo Complex in Fig. 1) which comprise larger land areas than primary habitat predicted by the habitat model. When we overlaid the 1994-2014 verified dataset on the major regions of bear habitat as defined in the 2001 study, 81% of harvest locations fell within those regions, compared with 95% reported for the 1990-1999 dataset. When we overlaid our verified sport-harvest locations on primary habitat produced by the 2015 habitat model, 83% of sport-harvest mortalities were within primary bear habitat, compared with the 2001 model that contained 71% of sport-harvest mortalities. We do not know why there is a discrepancy in the sport-harvest locations found in major regions of bear habitat between the 2 data sets, and reiterate our concern that they were not created using the same standards and therefore none of the model validity results should be compared.

Figure 1. Predicted black bear habitat in New Mexico from Costello et al. (2001).

^aThe quantity of habitat was derived from a model designed by G&F and T. Perry, PhD, and recent G&F research and population estimates. The habitat is classed as Excellent, Good, Moderate, and Fair; Excellent has a density of 3.0-4.0/100km², Good has a density of 1.2-1.7/100km², Moderate has a density of 0.6-0.9/100km² and Fair has a density of 0.4-0.5/100km² adult cougars. Densities derived from studies conducted in New Mexico. ~64% of the state is considered cougar habitat, 5% is tribal jurisdiction.

^bThe population estimated is that of independent cougars, ≥18 months of age.

^cCougar management aims for a stable population statewide with sustainable harvest levels into the future and is generally based on minimum population estimates. Stable = harvest ≤ 17% of total estimated population w/max of 30% female.

^d 90% of Total mortality limit and/or female sub-limit will close harvest in any zone, whichever occurs first.

^e Amount of cougar habitat was not used for the population point estimate; instead a density of 1.1 cougars/100 km² across the CMZ B and a density of 0.55 cougars/100 km² was used in CMZ Q based on G&F research using population models that account for spatial variation in cougar density.

a. Population estimates are based solely on primary habitat and do not include Secondary or Edge habitats.

b. The bear population estimate was derived from the NM Bear Study (Costello et al. 2001) and Gould et al. (2016) does not include populations on most tribal jurisdictions.

c. All BMZs will close when a number 10% below the harvest limit or female harvest limit is reached, whichever comes first. Only sport harvest is included in the harvest limit.

d. Population estimates for BMZs 1 and 10 were made across all habitat types given sampling distribution was not limited to primary habitat. Reported densities are conversions of those populations estimates for the zone to the number of bears per 100 km² of primary habitat for that zone for the sake of comparison to previous estimates for other zones.

SCIENTIFIC REPORTS

OPEN

A Bayesian state-space model using age-at-harvest data for estimating the population of black bears (*Ursus americanus*) in Wisconsin

Maximilian L. Allen^{1,2,3}, Andrew S. Norton⁴, Glenn Stauffer², Nathan M. Roberts², Yanshi Luo⁵, Qing Li^{5,6}, David MacFarland² & Timothy R. Van Deelen³

Population estimation is essential for the conservation and management of fish and wildlife, but accurate estimates are often difficult or expensive to obtain for cryptic species across large geographical scales. Accurate statistical models with manageable financial costs and field efforts are needed for hunted populations and using age-at-harvest data may be the most practical foundation for these models. Several rigorous statistical approaches that use age-at-harvest and other data to accurately estimate populations have recently been developed, but these are often dependent on (a) accurate prior knowledge about demographic parameters of the population, (b) auxiliary data, and (c) initial population size. We developed a two-stage state-space Bayesian model for a black bear (*Ursus americanus*) population with age-at-harvest data, but little demographic data and no auxiliary data available, to create a statewide population estimate and test the sensitivity of the model to bias in the prior distributions of parameters and initial population size. The posterior abundance estimate from our model was similar to an independent capture-recapture estimate from tetracycline sampling and the population trend was similar to the catch-per-unit-effort for the state. Our model was also robust to bias in the prior distributions for all parameters, including initial population size, except for reporting rate. Our state-space model created a precise estimate of the black bear population in Wisconsin based on age-at-harvest data and potentially improves on previous models by using little demographic data, no auxiliary data, and not being sensitive to initial population size.

Population estimates are essential for making decisions about management and conservation of many species^{1,2}, but often are difficult or expensive to obtain across large geographical scales^{2,3}. This is particularly true of mammalian carnivores^{4,5}, which are cryptic and difficult to count directly^{6–8}. Consequently, carnivore managers often base their population estimates on extrapolations from small data sets and adjust harvest quotas based on subjective opinion from the public and experts⁹. The importance and challenges of estimating wildlife populations has led to many different estimation methods^{2,10}, and more are developed each decade (e.g.,^{11–13}). For hunted populations, models using age-at-harvest data are often most practical, especially when working with a population across large scales when other methods of collecting data are difficult^{2,13}. Several rigorous statistical approaches, including both frequentist and Bayesian statistics, have recently been developed that use age-at-harvest and integrate auxiliary data (usually other harvest or demographic data) to accurately estimate populations^{3,11–13}. To date there has not been a model developed that creates accurate estimates without integrating auxiliary data, which makes it necessary for large field projects to collect demographic data. Bayesian state-space models may be able to accomplish this, as one of their main strengths is that they appropriately use regularization to share information

Figure 1. The number of harvested black bears in Wisconsin from 1971–2015, with no bear harvest in 1985. The number of harvested bears in each county is noted by a different color.

across space and time in the model¹¹, and may efficiently use all available data compared to other modeling approaches¹³.

Bayesian models can improve upon deterministic methods by being less reliant on prior information and allowing variation in parameters over time. Deterministic methods can sometimes be limited in accuracy^{11,14}, because they rely on assumptions that demographic parameters are stable over time (e.g.,^{13–15}), and can be biased when erroneous or subjective demographic parameter values are used^{2,13–16}. The Bayesian state-space modelling approach allows the modeler to transparently provide biologically supported information and constraints on parameters as priors, but the models use these as a starting point and the posterior values are not dependent on the prior values provided. Bayesian state-space models are also similar to stochastic population models, in that they reduce potential bias by allowing the demographic parameters to vary over time^{3,13}. Bayesian state-space models also allow for a range of information in parameters, from completely informative parameters similar to a deterministic accounting model to uninformative parameters similar to frequentist approaches, formalizing a process to transparently accommodate expert opinion when estimating wildlife populations. Drawbacks of Bayesian models is that they can be more complex and difficult to comprehend and more computationally intensive to implement than simpler models. Their implementation, however, could result in better decision-making about populations and harvest quotas, and lead to more effective monitoring and management, particularly for cryptic species.

Black bears (*Ursus americanus*) are a K-selected (e.g., Pianka 1970), spatially dispersed solitary carnivore^{17–20}. Black bears are a widely distributed species across North America, with many populations expanding in recent years²¹. In Wisconsin, black bears are a widespread game animal whose population and harvest have increased over the last few decades^{22,23} (Fig. 1). Most black bears in Wisconsin are found in the northern half of the state, but the population has been expanding southward in recent years. Since 1985 the Wisconsin Department of Natural Resources (WDNR) has estimated bear populations using a deterministic accounting model²². However, an independent capture-recapture estimate generated from tetracycline marking found that the current model underestimated the population size by nearly 2/3²². This is mainly due to the inability of the deterministic model to account for variation in harvest and population demographics over time and because the model incorrectly assumes a linear relationship between independent bear abundance estimates from bait stations and population abundance²⁴. Independent population estimates have allowed the WDNR to more accurately assess the black bear population in the state²², but these are expensive and often conducted years apart. Consequently, there is a need to update the population models in Wisconsin, as well as in many other states and jurisdictions.

K-selected species, including black bears, are susceptible to over-harvest²⁵, and management agencies need to carefully track populations when setting harvest quotas and goals. Bayesian state-space models may be ideal for estimating wildlife populations¹³, but have been used less frequently by wildlife managers to date (but see^{11,13}). Our goal was to create and evaluate a Bayesian state-space model using age-at-harvest data to estimate the statewide abundance of black bears in Wisconsin. Our objectives were to (1) determine reasonable prior distributions using literature review and harvest data; (2) compare abundance estimates to estimates from the capture-recapture estimates using tetracycline marking from 2011²⁶ and the population trend to the trend from catch-per-unit-effort for the state; and (3) analyze the sensitivity of the state-space model's population estimate to different specifications of the prior distributions for each demographic parameter and initial population size.

Materials and Methods

Study Area. Our study focused on the black bear population for the entire state of Wisconsin (Fig. 2), where the WDNR manages bears in 4 hunting zones (Supplementary Material 1). Most of the bear population is in the northern half of Wisconsin (hunting zones A, B, and D), and each zone has unique quotas and hunting regulations²². Over the course of our study the bear season began on the first Wednesday after Labor Day and was open for 35 days. Our methods were carried out in accordance with approved guidelines from the WDNR and University of Wisconsin, because we only performed analyses of harvest data did not include any experimental protocols or handling of animals. All data collected by the WDNR is archived by WDNR data scientists and is

Figure 2. Study area of Wisconsin in gray, and quasi-study area of the northern mixed forest ecotone. We used the quasi-study area to restrict the scope of the literature review of black bear studies to develop appropriate prior distributions for demographic parameters. The figure was created with ArcGIS 10.3 (www.arcgis.com) with the National Geographic open data layer base map (<http://www.esri.com/news/arcuser/0312/files/ng-basemap.pdf>).

fully available to the public. The data used for analyses in this manuscript are available within the manuscript and associated supplementary material.

We used reasonably informative prior distributions for the model parameters. Because information from Wisconsin for such prior distributions was sparse, we relied on studies from surrounding areas. To limit potential bias due to variation between Wisconsin and other study areas (e.g.,²⁷), we defined a quasi-study area based on habitat. We used areas in the northern temperate mixed forest ecotone (Fig. 2), in an attempt to match the habitat of the three northern Wisconsin bear zones. We included all mixed deciduous, coniferous and broad-leaved forest types delineated by Bailey²⁸ in ArcGIS 10.4 (ESRI, Redlands, CA) to create the quasi study area (Fig. 2). We reviewed estimates (or data when available) from all available peer-reviewed literature from within the quasi-study area to set relevant prior distributions for model parameters.

Population Size Parameters. Our goal was to estimate the total abundance (N) of the black bear population in Wisconsin immediately preceding the hunting season. We denote this population size as $N_{a,s,y}$, where a , s , and y , respectively, denote age, sex, and year for the indicated population size. We initialized the model with $N_{total} = 21,450$ in 2009, based on estimates from the WDNR (Supplementary Material 2a). Proportions of N_{total} in each age class were approximations based on the mean proportions observed in each age class in the bear harvest over the previous 30 years. As with most other population models, we assumed that harvest was proportional to the population for each age class. We therefore visually assessed the harvest proportion by age class over 30 years and found similar proportions despite increases in harvest, and therefore considered the proportions accurate enough for use in a Bayesian modelling framework, which uses the priors to inform the posteriors of the model.

Harvest Data. Our harvest data included:

O = observed total harvest by year (y), which we assumed to be a complete count of legal harvest.

C = number of harvested bears with known age (a) and sex (s). In the model, a is written as 10 age classes (1.5-year-olds, 2.5-year-olds, ..., 9.5-year-olds, >10.5-year-olds), excluding cubs (0.5-year-olds) that cannot be legally harvested.

We used 8 years (2009–2016) of black bear harvest data from Wisconsin. Since 1973, the WDNR has required bear hunters to register all harvested bears. We used these data to account for the total annual observed harvest. Sex of animals was recorded, and a tooth was extracted from each animal and submitted to Matson's Lab

Table 1. Review of mean litter sizes from studies in the northern hardwood ecotone, listed in order of sample size. Litter sizes are split into all litter sizes, and those for first litters and later litters. ^aIn a natural system. ^bIn a system with access to garbage. We provide the sample size (n), mean litter size (LS), and the range of litter sizes. Cases where data is not available are marked as not available (n/a).

(Milltown, MT, USA) for aging through analysis of cementum annuli²⁹. In a small proportion of bears, accurate aging was not possible. Thus

$$O_y > \sum C_{a,s,y}.$$

Recruitment Parameters. Our recruitment variables included:

LS_a = age-specific mean litter size of black bears,

PR_a = age-specific pregnancy rate (annual probability of giving birth), based on the proportion of bears that have first litters at given ages, then the interbirth interval for subsequent litters,

SP_s = proportions of newborn cubs that are female and male.

We reviewed the literature on cub survival to specify prior distributions for:

$CubSa$ = Cub survival from birth to the beginning of the first harvest season,

$CubSb$ = Cub survival from the beginning of the first harvest season to the beginning of the second harvest season.

Because it is illegal to harvest black bear cubs, bears do not enter the harvest model until they reach 1.5 years of age (immediately preceding the harvest season). Age-specific fecundity values (as number of 1.5-year-olds entering the model, per female) were calculated as:

$$Fec_a = LS_a \times PR_a \times CubSa \times CubSb$$

and multiplied by the number of females in each age class of the previous year to determine the number of 1.5-year-olds entering the population and by SP_s to determine the proportion by sex. We back-calculated the number of 0.5-year-olds in the population model as:

$$N_{0.5,s,y-1} = N_{1.5,s,y} / CubSb$$

Based on our literature review, we assumed that 0.5- and 1.5-year-old bears did not produce any cubs, but that a small proportion of the 2.5-year-old bears would have given birth at 2 years of age, and we therefore defined 4 fecundity age groups (2.5, 3.5, 4.5, and 5.5+ year-olds). These age groups are aggregated differently from the groups defined for abundance, but the subscript a denotes actual age (except for the absorbing terminal age of the 10.5+ -year-old age class), so its use is consistent.

To specify prior distributions for LS_a we reviewed literature from our quasi-study area (Table 1). Because of substantial differences in litter sizes between first and subsequent litters we used data only from studies from which we could determine values for first and/or subsequent litters, and then used these studies to parameterize the prior distributions (Table 2).

To specify prior distributions for PR_a we used birth data from Wisconsin black bears determined through cementum annuli techniques³⁰. To determine the age-specific probability of having a first litter, we used data from 1989 to 2008, and calculated the annual mean proportion of bears giving birth for the first time for each age class. We also used the interbirth interval values provided by the authors³⁰, used these hyperparameter values for the prior distributions (Table 2).

To specify prior distributions for SP_s we reviewed literature from our quasi-study area, but found only one study¹⁹ with robust sample sizes (e.g., $n > 20$) and therefore used the values from that study as our hyperparameters for the prior distributions (Table 2).

For cub survival data ($CubSa$ and $CubSb$; Table 3) we reviewed literature from our quasi-study area to determine the prior distribution and hyperparameters (Table 2).

Recruitment Parameters				
Variable	Parameter	Mean	Distribution	
LS-a	Litter Size 2.5-year-olds	2.00	Gamma (20,10)	
LS-b	Litter Size 3.5-year-olds	2.00	Gamma (20,10)	
LS-c	Litter Size 4.5-year-olds	2.00	Gamma (20,10)	
LS-d	Litter Size 5.5+ year-olds	2.74	Gamma (16.4,6)	
PR-a	Pregnancy Rate 2.5-year-olds	0.003	Beta (2.61,1000)	
PR-b	Pregnancy Rate 3.5-year-olds	0.25	Beta (34,100)	
PR-c	Pregnancy Rate 4.5-year-olds	0.53	Beta (54,48)	
PR-d	Pregnancy Rate 5.5+ year-olds	0.48	Beta (47,50)	
SP	Sex Proportion (female)	0.46	Beta (426, 500)	
Survival Parameters				
Variable	Parameter	Mean	Long-Term Precision	Annual Precision
HSm	Male Harvest Survival	0.77	3	Gamma (20,0.5)
HSf	Female Harvest Survival	0.85	3	Gamma (20,0.5)
NS	Non-harvest Survival	0.95	4	Gamma (20,0.5)
CubSa	Cub Survival years 0.0–0.5	0.84	4	n/a
CubSb	Cub Survival years 0.5–1.5	0.71	4	n/a
Rep	Recovery Rate	0.98	2	n/a

Table 2. Prior distributions and hyperparameters in our statewide Bayesian state-space model using age-at-harvest data, split into recruitment and survival parameters. We include the variable, parameter description (for gamma distributions these are the shape and rate), mean and distribution used. For survival prior distributions the means are given at the real parameter scale and long-term and annuals precisions (1/variance) are at the link scale (loglog).

Table 3. Review of black bear survival from studies in the northern hardwood ecotone, listed in order of sample size. Survival values are split by sex with values for annual survival, harvest season survival, and for non-harvest season survival, when available. We list the sample size (n), the mean survival estimate, and the range of survival values provided. Cases where data were not available are marked as not available (n/a). *Reported for males and females combined. ⁺51 bears in total.

Survival Parameters. Our survival variables included:

$HS_{a,s,y}$ = age-, sex-, and year-specific survival during harvest season,

NS_y = age- and sex-specific survival outside of harvest season,

Figure 3. Life cycle diagram of black bears used to construct the stage-structured population matrix.

$Rep_{s,a}$ = sex- and age-specific recovery rate of bears during hunting season (percentage of hunting season mortality related to legal, reported harvest),

LHR_a = age-specific offset term for complementary log-log survival during the hunting season.

Harvest rate, noted as:

$HR_{a,s,y}$ = age-, sex-, and year-specific harvest rate,

was then a latent variable calculated annually as

$$HR_{a,s,y} = (1 - HS_{a,s,y}) \times Rep_{a,s}$$

Age- and sex-specific survival was then calculated annually as:

$$S_{a,s,y} = HS_{a,s,y} \times NS_y$$

For adult survival parameters (HS_s , NS , and $Rep_{a,s}$) we reviewed literature from our quasi-study area (Table 3), to determine the prior distributions and hyperparameter values (Table 2). We based the distribution and mean for reporting rates on a pair of studies from Ontario³¹ and Minnesota¹⁹. Because Wisconsin requires registration for every animal harvested, the reporting rate in Wisconsin is thought to be nearly universal and noticeably higher than reporting rates in Minnesota where registration is voluntary, and consequently we based the mean on the study from Ontario (Table 2), where every hunter was sought out³¹.

Parameter Summary. In summary, our modeled population parameters are: N_y , LS_a , PR_a , SR_s , $HS_{a,s,y}$, NS_y , $CubSa$, $CubSb$, and $Rep_{a,s}$, and the harvest data are $O_{s,y}$ and $C_{a,s,y}$. All other parameters (latent parameters) were derived from the basic parameters (e.g., $HR_{a,s,y}$). Regularization of parameter estimates was achieved by construction of informative prior distributions for each modeled parameter, based on information about black bear ecology.

Modeling Framework. Our state-space model consisted of two process models whose likelihoods were jointly modeled^{13,32}. The population process model (Fig. 3) was based on the unobserved/latent population state process (that progresses from the initial state density to sub-state transitional densities [hunting season, non-hunting season, recruitment]), and the observation state process was based on observed harvest data^{13,33}. We used Markov Chain Monte Carlo (MCMC) methods to approximate posterior distributions¹³ and based our inference on posterior summaries of the MCMC samples.

Our population process model was constructed as a two-sex, ten-stage population projection matrix¹⁰. The age distribution for the starting population in year 1 was specified by our prior distribution. In subsequent years, abundances for age classes ≤ 2 were derived as

$$N_{a,s,y} = N_{a-1,s,y-1} \times S_{a-1,s,y-1}$$

The abundance of the terminal age class in years 2 – Y was

$$N_{A,s,y} = N_{A-1,s,y-1} \times S_{A-1,s,y-1} + N_{A,s,y-1} \times S_{A,s,y-1}$$

because this was an absorbing age class. Abundance in the first age class in year $y = 2$ to Y was dependent on survival of cubs produced in year $y - 2$, and was derived as:

$$N_{1,s,y} = SP_s \times CubSa \times CubSb \times \sum_{a=1}^A N_{a,1,y-2} \times Fec_a$$

Variable	Description	PRC	CV

Table 4. Parameters tested for sensitivity to prior distributions, with resulting percent relative change (PRC) and error measurements as coefficient of variation (CV) in the Bayesian state-space model.

Because N_{y-2} was not defined when $y=2$, we made the necessary simplifying assumption that $N_{a,1,y-2} = N_{a,1,y-1}$ when $y=2$.

Our observed-harvest data model consisted of two parts: total observed harvest (**O**) and harvested bears that have been aged and sexed (**C**). This is necessary because only a subset of the legal harvest is aged and sexed, due to broken teeth, lost samples, or other problems. Because the harvest likelihood was constructed across all age groups each year, variation will only include sampling variation¹³.

Statewide State-Space Model. We created a ‘statewide’ state-space population model, to estimate the black bear population in the entire state of Wisconsin using actual harvest data from 2009–2016 and our prior distributions (Table 2). We fit our models in Program R³⁴ using JAGS³⁵ and the R package *rjags*³⁶ (full code available in Supplementary Material 3). We ran 220,000 iterations with 3 chains, a burn-in of 20,000, and a thinning rate of 4. We visually assessed the convergence and mixing of the chains, and used Gelman-Rubin statistics to determine convergence³⁷. We visually compared the posterior abundance prediction for 2011 with WDNR capture-recapture estimates based on tetracycline marking from 2011²⁶. We also compared the posterior abundance trend, and the WDNR abundance trend from the 2017 model (Supplementary Material 2b), to the trend of catch-per-unit-effort (CPUE, calculated as annual harvest divided by annual hunting permits issued) for Wisconsin using linear regressions.

Assessing Sensitivity of State-Space Model Parameters. We essentially used only harvest data from Wisconsin, although independent auxiliary data can be used to increase the precision of parameters in state-space models when needed¹³. To understand how the hyperparameter values of our prior distributions affected the accuracy of state-space model performance, we compared the results of our statewide state-space model to models run with bias in individual parameters. We considered 10% positive and negative biases for the mean and variation of the prior distributions for 9 parameters, totaling 18 different scenarios (Table 4). In each of the 18 models for the sensitivity analyses, the hyperparameter values for each parameter were exactly the same as our statewide model except for the parameter being tested.

As with the statewide population model, we ran the models from the sensitivity analyses using 220,000 iterations in 3 chains, with a burn-in of 20,000 and a thinning rate of 4. We used Gelman-Rubin statistics to determine convergence³⁷, where we considered any values < 1.1 to indicate convergence.

To evaluate the sensitivity of the state-space model to each scenario we calculated percent relative change (PRC) in population as:

$$PRC = \frac{\sum_{y=1}^Y \left(\frac{\hat{N}_y - N_y}{N_y} \right)}{Y} \times 100,$$

and the coefficient of variation (CV) as:

Figure 4. A comparison of our statewide population estimates and 95% credible intervals from the Bayesian state-space model (SSM, in brown) for Wisconsin (2009 to 2017) and the 2017 WDNr population estimate trend (in green). Also shown for comparison are the WDNr population estimate from 2009 (the initial population size for our SSM), the statewide trend in catch-per-unit-effort (CPUE, on the secondary y-axis in light blue), and the independent capture-recapture population estimate (for bears 1.5+) from tetracycline marking in 2011 with 95% confidence intervals (in dark blue).

$$CV_{pop} = \frac{\sqrt{\frac{\sum_{y=1}^Y (\hat{N}_y - N_y)^2}{Y}}}{\bar{N}} \times 100$$

for comparison between models, where \hat{N} is an abundance estimate from the sensitivity model and N is an abundance estimates from our statewide population model.

Results

Statewide Population Model. We used a Bayesian state-space model to estimate the statewide black bear population in Wisconsin using harvest data from 2009–2016. The observed mean harvest (O) was 4425 (± 140 SE) bears and ranged from 3952 to 5133 bears (Supplementary Material 4). Bears with known age and sex (C) comprised, on average, 85.9% of the harvest (Supplementary Material 4).

The statewide population estimates indicated a decreasing trend in the black bear population from 2009 to 2017 (Fig. 4). The annual variation and 95% credible intervals were similar, but increased slightly in the final two years of estimation (Fig. 4). The population abundance estimate for 2011 was visually similar to the independent tetracycline estimate for 2011 (Fig. 4). The population trend estimate had a significant and strong correlation with CPUE ($df = 8$, $R^2 = 0.93$, $p < 0.0001$), while the 2017 population trend from WDNr model had a non-significant correlation with CPUE ($df = 8$, $R^2 = 0.36$, $p = 0.09$).

The posterior distributions and means did not differ greatly from the prior distributions and means for litter sizes (Supplementary Material 5a), pregnancy rates (Supplementary Material 5b), and sex proportion of cubs (Supplementary Material 5c). Conversely, posterior distributions for harvest season survival for each sex and year (Supplementary Material 5d) were considerably more informative than the prior distributions. Compared to the prior distributions the means of the posterior distributions for harvest survival were generally slightly lower for females and were lower in all cases for males (Supplementary Material 5d). Harvest survival for younger age classes (1.5, 2.5, and 3.5 year-olds) was lower than for older age classes, and varied among years with 2011 and 2016 having the lowest survival estimates (Supplementary Material 5). The means of the posterior distributions for non-harvest season survival for each year was higher than the means of our prior distributions, but precision did not greatly improve (Supplementary Material 5e). Similarly, the means of the posterior distribution for cub survival for both periods were slightly greater than the means of the prior distribution, and precision improved only slightly (Supplementary Material 5f). The posterior distribution for the reporting rate were more informative than the prior distribution for females, but for males the posterior distribution had slightly greater variance than the prior distribution (Supplementary Material 5g). The means of the posterior distribution for the initial population size were generally slightly lower than the means of the prior distribution for males, and generally slightly higher for females (Supplementary Material 5h).

Sensitivity of Statewide Population Model. Based on the PRC values, our population model estimates were most sensitive to potential bias in the reporting rates, with a 10% underestimate of the reporting rate led to a PRC of 7.33 ($CV = 7.26$). The model was robust to potential bias in all other parameters, which had PRCs of < 2.00 (Table 4). A posthoc test of 50% bias in the initial population resulted in PRCs of -7.60 ($CV = 7.66$) for an underestimate and 11.88 ($CV = 12.03$) for an overestimate.

In each sensitivity test the models closely tracked the slightly decreasing trend and abundance estimates of our statewide state-space model. The potential bias of each variable also resulted in the expected population effects (increase or decrease of estimate), except in the cases of non-harvest season survival and cub survival for period

B. In these cases, the underestimate of non-harvest season survival led to an increase in the population estimate, and an underestimate of cub survival led to an increase in the population estimate while an overestimate led to decrease in the population estimate (Table 4).

Since the current model used by the WDNR is sensitive to the initial population estimate, we also performed two post hoc tests that assessed the sensitivity to extreme bias (50% increase and decrease) in the initial population estimate. The 50% underestimate had a PRC = -7.60% (CV = 7.67) for the population estimate, and the 50% overestimate had a PRC = 11.88% (CV = 12.03).

Discussion

We fit age-at-harvest data from 2009 to 2016 to a Bayesian state-space model to create an accurate and precise estimate of black bear population abundance in Wisconsin. To assess the relative accuracy of our model we compared the 2011 abundance estimate to an independent capture-recapture population estimate from 2011²⁶ (Fig. 4), and compared the abundance trend of our model to the trend of catch-per-unit-effort for the state. We found a strong correlation in trend with the catch-per-unit-effort from the state, with both estimating a decreasing trend, and similar abundance estimates to the independent abundance estimate from 2011. Our model for black bears appears to be a marked improvement on the population estimation model currently used by the WDNR (e.g.,²²), by increasing the precision of the population estimate, providing estimates of variance in the estimate, and being independent of the initial population size values. By using Bayesian analyses, we allowed our model to use our prior information to create accurate posterior estimates, which can vary among years and age classes. Our population estimates were also generally robust to bias in the prior distributions for all parameters, except for reporting rate. These results support previous conclusions about the usefulness and applicability of Bayesian state-space models using age-at-harvest data for population estimation (e.g.,^{11,13}), but now extend to situations lacking auxiliary demographic or other data from the population. Our state-space model appears to be a valid proof of concept for modeling wildlife populations; and Bayesian state-space models are a valuable tool to be added to the available analytical techniques for populations.

A strength of our state-space model was its robustness to biased prior distributions, including initial population size. The PRC values for all parameters were <2%, except for reporting rate (Table 4), and even a 50% biased estimate of initial population size led to PRC values of <12%. This is encouraging, because we derived many of our prior distributions from literature values and lack of information about parameter values can cause problems in many population estimation models (e.g.,²), especially when models are sensitive to parameters that are determined by expert opinion that can itself be biased⁹. We primarily used parameters that were derived from literature review from black bear studies in the northern mixed forest ecotone. These are informed values that help the model perform better than completely uninformed parameters and similar data are generally available for most harvested species across North America. Many population models, especially deterministic models, are sensitive to initial population size¹⁶, but being robust to bias in these estimates is a key strength of this model, especially when considered for use by management agencies. Considering how robust the state-space model is to biased prior distributions, and the applicability of using prior distributions informed by the literature review, the priority for future work should focus on accurately determining the reporting rates, potentially in the form of surveys.

Age-at-harvest models are clearly dependent on the quality of age-at-harvest data available to fit to the model. Our model was robust to bias in prior distributions partly because the quality of age-at-harvest data collected for bears in Wisconsin is excellent and broken down into specific age classes rather than general age stages (juvenile, yearling, adult). Consequently, survival probability was well-estimated in our model. Population models, especially for long-lived species such as black bears, often are most sensitive to adult, particularly female, survival probability (e.g.,^{2,16}). Non-harvest mortality for black bears is typically low^{38,39}, and therefore the focus of most research is on harvest survival. Our model inference supports this focus, in that estimates for non-harvest survival were considerably greater than for harvest-season survival, even though the harvest season is much shorter than the non-harvest season²². We did not account for the potential of additive versus compensatory mortality, but this should be considered in future analyses. Our state-space model, however, shows that harvest season survival can be precisely estimated using only age-at-harvest data, assuming quality data are available, and informative prior distributions on other parameters can be reasonably constructed. In cases where less age-at-harvest data is available, auxiliary data can be integrated into the model to potentially improve the precision of the estimates. Examples of data that can be incorporated include annual independent population estimates or observation surveys, survival estimates or other demographic parameters, or other covariates that affect demographic parameters such as winter severity or snow depth¹³. These results underscore the usefulness of sex and age data that are collected by many management agencies for harvested animals, and agencies interested in using state-space models to estimate populations should continue to collect this information.

The posterior distributions for recruitment variables were similar to the prior distributions, indicating that our prior beliefs were not updated by the model. The lone parameter that used data from Wisconsin (other than initial population size) was interbirth interval and proportion of age at first litter data (from³⁰), therefore, the litter size values from the literature could potentially have underestimated litter sizes in Wisconsin. Black bear fecundity is strongly linked to food^{17,19}, with heavier and older females producing more cubs^{40–43}, particularly those with access to human foods¹⁷. There are few restrictions on the amount or frequency of bait that can be placed for black bears in Wisconsin⁴⁴, which differs from some other jurisdictions, and as a result >40% of food consumed by the bear population is from intentional bait⁴⁴. Access to this extra nutrition may lead to relatively larger litter sizes in Wisconsin compared to other areas, and therefore may lead to higher fecundity rates than currently reported in the literature. Given the robustness of the model to bias in fecundity parameters, however, this may not greatly affect the abundance estimates.

We based the initial proportions of bears in each sex and age class on the proportion of the harvest for each class. The prior distributions we used were reasonable, but were improved by the estimated posterior distribution.

The posteriors were generally slightly lower than the prior distributions for males and generally slightly higher for females (Supplementary Material 5h). This is likely due to male bears being more frequently harvested⁴⁵, and these proportions in the prior distributions can be adjusted to account for the potential bias we introduced, which would likely allow the model to converge more quickly. By using a Bayesian modeling framework, the model was able to account for potential bias in the prior values, which is important when assuming that the harvest among age classes is proportional to their abundance in the population. When implementing the model for management and conservation, instead of using the independent population estimates to proof the model abundance estimate, we suggest using the independent population estimates as the starting population values. It is also important to perform independent population estimates every 3–5 years to improve the model precision over time, and ensure the abundance estimates are realistic (e.g.,²²).

Although our model is a valid proof of concept for updating population estimation in Wisconsin and other states, management agencies should adjust and fine-tune the model to match regionally and management zone specific conditions before using for management and setting quotas. This model is based on a statewide data, and produces only statewide estimates, but most states (including Wisconsin) are split into management zones. Management models should be split into an estimate for each zone, and managers can consider setting zone-specific prior distributions based on the unique ecology and hunting culture of each zone. The state-space model allows for precise estimates of wildlife populations, including for K-selected species which are vulnerable to over-harvest, making it valuable in both management and conservation settings. Due to budgetary constraints, many agencies are considering ways to reduce spending, but our model has shown the value of long-term age-at-harvest datasets.

Our harvest model was for black bears, but a similar model can be built for other harvested species, and, if needed, other data can be integrated into the model to increase the accuracy of the population estimate. Bayesian state-space models have now been successfully used for black bears and white-tailed deer (*Odocoileus virginianus*¹³), and similar models could be used for other harvested species that have a reasonable number of individuals in the harvest with known sex and age. Our model worked well partly because the WDNR has attempted to age and sex every harvested bear, but the state-space models also perform well when only a small proportion (e.g., 5%) of animals are aged¹³. Most management agencies have collected sex and age data for harvested animals over the course of decades, and our model should be widely applicable to agencies. In addition, we were able to create reasonable population estimates without using auxiliary data, which is a step forward for population models. Importantly, Bayesian state-space models are flexible, and can be adjusted to any harvest system, including those with unique data or parameters.

(Garshelis 1990). Barnhurst (1986) investigated the vulnerability of cougars to sport hunting as a step toward understanding how to interpret harvest data. He proposed that vulnerability to harvest would be related to the frequency at which differing sex- and age-class cougars cross roads because cougars are generally hunted using trailing hounds, typically from roads or trails. The vulnerability index he developed from road-crossing frequencies suggested that transient males were most vulnerable, followed by resident males, transient females, resident females both without young and with young >6 months old, and finally resident females with young ≤6 months old.

Conceptually, the likelihood of a specific sex or age class of cougar being harvested would reflect its relative abundance in the population multiplied by its relative vulnerability. The least-vulnerable individuals should become prominent in the harvest only after the population had been reduced in size by removal of more vulnerable cougars. Our objective was to test the hypothesis that sex and age composition of the harvest would vary predictably with population size in a cougar population primarily hunted using hounds.

Study areas

Experimental population

The Snowy Range, located in southeast Wyoming about 30 km west of Laramie, was a 2,760-km² timbered region including a 2,170-km² portion of the Medicine Bow National Forest surrounded by private, Bureau of Land Management, and state-owned lands. This terminal mountain range was surrounded by sagebrush (*Artemisia tridentata*) grasslands except on the southern end, where it was connected to contiguous habitat by a 14-km-wide segment of the Medicine Bow Mountains. Cougars occupied about 1,700 km² of this area during winter. Wyoming State Highway 230 on the west, United States Interstate 80 on the north, the Laramie River and Sand Creek drainages on the east, and Colorado highways 125 and 127 on the south bounded the Snowy Range. The area was topographically diverse, ranging in elevation from about 2,100 m in the valleys to 3,652 m at Medicine Bow Peak. Vegetation communities were dominated by sagebrush grasslands in the peripheral valleys; lodgepole pine (*Pinus contorta*) stands with interspersed quaking aspen (*Populus tremuloides*), Rocky Mountain juniper (*Juniperus scopulorum*),

and limber pine (*Pinus flexilis*) at mid-elevations; and Engelmann spruce (*Picea engelmannii*)-subalpine fir (*Abies lasiocarpa*) forests with occasional limber pine at higher elevations (Alexander et al. 1986). Understory dominants in the mid- and high-elevation communities included huckleberry (*Vaccinium scoparium*), buffalo berry (*Shepherdia canadensis*), serviceberry (*Amelanchier alnifolia*), snowberry (*Symphoricarpos* spp.), and common juniper (*J. communis*). Riparian areas were composed primarily of willow (*Salix* spp.) with interspersed narrowleaf cottonwood (*P. angustifolia*) at low elevations.

Abundant roads provided good access to most cougar habitat in the Snowy Range. Annual harvest was relatively constant during the 5 years before our study, ranging from 9–12 cougars.

Comparison population

The northern portion of the Laramie Range included an isolated mountain range near the cities of Casper and Wheatland in southeast Wyoming and encompassed 2,960 km² of timbered habitat. Elevation ranged from 1,620 m in the eastern valleys to 3,132 m at Laramie Peak. Ponderosa pine (*P. ponderosa*) stands dominated low to mid elevations, with lodgepole pine common at mid to high elevations. Low-elevation, nonforested regions and interspersed meadows were vegetated by grasses, forbs, and shrubs. Riparian areas consisted primarily of willow with occasional aspen pockets. Other forest species occurring at low levels included limber pine, subalpine fir, Douglas-fir (*Pseudotsuga menziesii*), and Engelmann spruce.

Annual harvest in Laramie Peak averaged 11 cougars during the 5-year period before harvest treatment, ranging from 7–16 cougars per year. The Wyoming Game and Fish Department changed its management objective from sustained harvest of a stable to increasing population to reducing the population through increased harvest in 1996 and increased harvest quotas from 10 to 34 for the next 7 seasons. Regional Wyoming Game and Fish Department personnel believed the Laramie Peak cougar population was at a relatively high density prior to 1996 based on increased cougar sightings, depredation incidents, and hunter interviews.

Methods

We trailed cougars using hounds and immobilized them upon capture with a mixture of 5 mg/kg

Telazol® (Aveco Co., Inc., Cherry Hill, N.J.) and 1 mg/kg xylazine hydrochloride delivered in a hypodermic dart fired from a CO₂ pistol; we reversed the effects of xylazine hydrochloride using yohimbine hydrochloride (0.15 mg/kg). We tagged independent cougars (>1 year old and solitary) with standard VHF radiocollars (Model 9D, warranty battery life=3 years) and dependent young with 22-g ear-tag transmitters (Model 7PN, warranty battery life=295 days; Advanced Telemetry Systems, Inc., Isanti, Minn.); we equipped transmitters with mortality-sensing options. We also attached a uniquely numbered ear tag to all captured cougars. We recorded sex, age, weight, and morphometric measurements at capture. We estimated age (juvenile <1 year, subadult 1–2.5 years, adult ≥3 years) from tooth wear, canine ridge eruption, spotting progression, and evidence of previous lactation for females (Shaw 1979, Ashman et al. 1983, Lindzey et al. 1989, Laundre et al. 2000) or known birth date for cougars born to radiocollared females based on female denning behavior. We located radiotagged cougars weekly from fixed-wing aircraft between December 1997 and May 2001 and once per month from June 2001–April 2003.

We used radiotelemetry to identify female denning behavior (consecutive locations at the same location), timing of family breakup, and emigration of subadults. We assumed emigration when an individual dispersed from its mother, had not yet exhibited territorial behavior, and we were no longer able to detect its radio signal. We estimated age of juveniles of unknown birth date by applying the growth-curve models developed in the Northern Great Basin (Laundre and Hernandez 2002) after adjusting them for differences detected when comparing model estimates to size of known-age juveniles in the Snowy Range (C. R. Anderson, unpublished data).

Experimental design

We manipulated size of the Snowy Range cougar population using regulated hunter harvest to reduce and then allow recovery of the population; all cougars harvested during the study except 2 were taken using hounds. The cougar-hunting season was open from 1 September–31 March, but most cougar harvest did not occur until mid-November, when snow conditions were adequate for tracking cougars using trained hounds; >90% of cougars harvested in Wyoming were taken using hounds (Wyoming Game and Fish Department

2003). Annual harvest levels were regulated by a quota system in which the season was closed if the quota was met before 31 March. Young (<1 year old) cougars and females with young at side were legally protected from harvest. We concurrently monitored sex and age composition of the population and the harvest and annually tested predictions of harvest composition based on abundance of sex- and age-class cougars in the population and their relative harvest vulnerability (Barnhurst 1986). We predicted that harvest composition would be predominantly subadults (possibly more females) during the pretreatment year (high density, low harvest), shift to adult males during the first year of treatment (from high to moderate density, high harvest), shift from adult males to adult females during the second treatment year (from moderate to low density, high harvest), and return to subadults during the post-treatment period (increasing population, low harvest) where the subadult segment would initially consist primarily of males and eventually consist primarily of females as the population approached pretreatment levels. We examined annual changes in harvest composition of adult males, adult females, and subadults using the Fisher's exact test; we applied 1-tailed tests to compare the first 4 seasons where changes were predicted and 2-tailed tests to examine the recovery period when composition was not expected to change greatly. We also examined the relationship between proportion of adults in the female harvest and estimated harvest rate using simple linear regression analysis, expecting adult female harvest composition to increase with harvest level.

We then compared harvest composition documented in the Snowy Range to that observed in Laramie Peak. Although we did not monitor density in this area, it represented a geographic population (i.e., occupied cougar habitat surrounded by inhospitable, unoccupied landscapes) similar to the Snowy Range, contained a similar amount of cougar habitat, had adequate hunter access to facilitate population reduction, and the population was exposed to harvest levels similar to those we applied in the Snowy Range before and during the treatment period. We assumed that harvest composition from this area would show similar trends to those documented in the Snowy Range if harvest composition changed predictably with population size in harvested populations. We tested for differences in annual harvest composition between populations using the Fisher's exact test (2-tailed). We

also determined ages from counts of cementum annuli of harvested adult females in both populations to determine whether age of adult females declined as the population declined following high harvest levels.

Age-class estimates

We assigned harvested and captured cougars to age class based on tooth wear, presence or absence of a canine ridge, evidence of spots or foreleg bars, evidence of previous lactation if female (Anderson and Lindzey 2000), and counts of bands in the cementum of premolars removed from harvested cougars. We first gave priority to evidence of previous lactation in females (subadult: nipples white and ~4–6 mm wide; adult: nipples dark or mottled and ~8–10 mm wide), followed by annuli age (subadult = 1–2 yr), canine ridge eruption (absent = subadult), and finally foreleg bars (dark = subadult or young adult) and spots (present = subadult or young adult). To evaluate reliability of our aging techniques, we compared ages estimated from counts of cementum bands to ages estimated with the other criteria for those cougars that were captured and later harvested.

Population estimates

During the first winter (Dec 1997–Apr 1998), we conducted intensive capture efforts in 2 regions of the Snowy Range to obtain an initial density estimate and to create a marked sample for subsequent mark-recapture efforts. We captured cougars in a 439-km² area in the southeast region and a 382-km² area in the west-central region of the Snowy Range; 90% of cougar harvests in the Snowy Range came from these primarily public land areas (Wyoming Game and Fish Department mountain lion harvest data base, Lander, Wyo.). We estimated density for the 2 areas by summing number of cougars marked and tracks of known, unmarked cougars. We included unmarked cougars only if track characteristics (identified as male or female via planter pad width and stride length; Fjelline and Mansfield 1988) and number and size of young accompanying a female suggested a unique individual and when tracks were located outside traditional use areas of radiocollared cougars identified from previous telemetry locations. The initial density estimates from the 2 areas were then applied to the remainder of cougar habitat in the Snowy Range to estimate population size for the study area. Cougar habitat was delineated using elevations and topography used by

radiocollared cougars February–April, 1998.

We applied the Lincoln-Peterson estimator (Pollock et al. 1990) to calculate annual, pre-hunting-season (autumn) population estimates of independent cougars. Post-hunting-season (spring) population estimates were pre-season estimates minus harvest removals and estimated natural mortality from our marked sample. We attempted to meet assumptions of the technique by modifying our sampling design and using information from radiotagged cougars. We addressed geographic closure by recapturing during late autumn and winter months when emigration and immigration were least likely (Ross and Jalkotzy 1992). We addressed the demographic closure assumption by adjusting for deaths based on records from radiocollared cougars and by considering young cougars in our marked sample independent at the mean age family groups became loosely associated (prior to dispersal), and thus available for recapture (e.g., harvest), by the beginning of the recapture period (15 Nov, average date of sufficient snow for hunting). Because cougar captures relied heavily on adequate snow conditions for tracking that varied temporally and spatially, maintaining equal capture effort throughout the study area was not possible and reduced our ability to assure equal capture probabilities across cougars. To minimize potential biases from capture heterogeneity and provide sufficient time to sample the entire study area, we treated the entire winter sampling period (15 Nov–31 Mar) as a single capture effort and counted each individual detected only once in the recapture sample regardless of the number of times they were actually detected. Because captured cougars remained ear-tagged throughout the study but transmitter failures occasionally occurred, we assumed individuals that had established territories prior to transmitter failure and that had been monitored until the previous summer were still in the population and available during the following winter recapture period; on 10 of 12 occasions where transmitters failed, marked residents were subsequently recaptured or harvested.

The capture sample was independent, radio-tagged cougars in the population at the beginning of the recapture sampling period (15 Nov) during both treatment and recovery periods. The recapture sample was cougars harvested by hunters during the hunting seasons of the treatment periods, but, because harvests were intentionally reduced during the recovery period (winters of 2000–2001,

2001–2002, and 2002–2003), we augmented the recapture sample by hunting the study area after hunters had finished. During our hunting we tagged and released unmarked cougars, recorded marked cougars recaptured, and recorded presence of individual, unmarked cougars (defined earlier) we were unable to capture. We included cougars marked in the population prior to 15 November each year in our initial capture sample and those captured from 15 November–31 March in our recapture sample. We recorded capture effort as number of hunter days for successful hunters (no data for unsuccessful hunters) and number of days spent tracking and capturing cougars by study personnel. Post-season population estimates were pre-season estimates minus harvest and mortality from other causes estimated from our marked sample during the recapture period. We estimated 90% confidence intervals around pre-season population estimates following Pollock et al. (1990). We estimated autumn sex and age composition of the population by adding unmarked cougars harvested during that year's hunting season to our sample of marked cougars.

Results

We tagged 16 independent and 13 dependent male and 17 independent and 15 dependent female cougars between December 1997 and February 2002. Twenty-one marked, independent cougars were harvested during the treatment and recovery phases of the project, and 9 marked cougars (5 adult males, 4 adult females) were alive at the end of the study. Cougar ages estimated using cementum annuli counts were in agreement with other aging criteria in 14 of 18 comparisons and within 1 year for 3 others (Anderson 2003). We noted that ages of dependent young of known birth date in the Snowy Range were consistently underestimated (\bar{x} = 1.47 mo, SD = 1.26, n = 13) using the Northern Great Basin growth-curve models (Laundre and Hernandez 2002) and therefore added the mean difference to estimate ages for litters of unknown birth date.

Dependent cougars

became independent at an average age of 14 months (range = 11–17 months, n = 7); 2 litters became independent following the death of their mother at 14 and 17 months old (1 natural, 1 harvest). Association among family members became progressively looser over the month before independence. Thus, to account for recruitment in our recapture sample, we included marked dependent young as subadults if they were 13 months of age by 15 November each season. Emigration occurred between April and September for 8 of 9 emigrants monitored; 1 subadult male emigrated during January.

Population estimates

We tagged 18 cougars in the study area and identified 6 others from tracks after 60 days of trapping and tracking in the southeast and 45 days in the west-central section of the Snowy Range during winter 1997–1998. We estimated independent cougar density at 3.42/100 km² in the southeast (15 cougars/439 km² × 100) and 2.35/100 km² in the west-central region (9 cougars/383 km² × 100). Cougar habitat in the Snowy Range during this period, estimated from characteristics of habitat used by marked cougars February–April 1998, was 1,720 km². We estimated 50 independent cougars in the Snowy Range in spring 1998 (45–55 depending on the density estimate applied). A harvest quota of 25 was then set for the next 2 hunting seasons (treatment; 1998–1999 and 1999–2000) to elicit the desired (about 50%) reduction in the Snowy Range cougar population.

Harvests were 25 and 17 cougars for the 2 treatment seasons, resulting in an estimated population of 20 independent cougars by spring 2000 (Table 1). Harvest quotas were then reduced to 6–8 cougars per season to facilitate population recovery.

Table 1. Pre (autumn) and post-harvest (spring) cougar population estimates^a from the Snowy Range, Wyoming, USA, autumn 1998–spring 2003. Note population decline following 2 years of high harvest and population increase following 3 years of light harvest.

Season	n_1	n_2	m_2	\hat{n}_{pre} (90% CI)	No. harvested	% natural mortality	\hat{n}_{post}
1998/99	15	25	6	58 (36–81)	25	11	30
1999/00	19	17	8	39 (28–50)	17	9	20

^a $\hat{n}_{pre} = [(n_1 + 1)(n_2 + 1) / (m_2 + 1)] - 1$, where n_1 = number marked and released in first sample, n_2 = number captured in second sample, and m_2 = number captured in second sample that were marked from first sample. $\hat{n}_{post} = (\hat{n}_{pre} - \text{harvest}) - [(\% \text{ natural mortality}) (\hat{n}_{pre} - \text{harvest})]$.

very. The population increased to an estimated 46 independent cougars by spring 2003 (Table 1). The number of hunter-days totaled 17 and 79 during the 2-year treatment period and 27, 50, and 21 days during the 3-year recovery period. High hunter effort during the second treatment year and the second recovery year were due to excessive time spent hunting by an individual hunter each year (50 and 36 days, respectively). We spent 60, 54, and 68 days tracking and marking cougars to augment the recapture sample during the recovery phase.

Cougar harvest composition in response to manipulation

Cougar harvest ($n=22$) composition during the pretreatment period was composed primarily of subadults (46%, 1–27%, 30) followed by adult males (25%) and finally adult females (14%, Figure 1). As harvest levels increased and the population declined in size, there was an initial increase (40%) followed by a decrease (24%) in proportion of adult males in the harvest and a consistent increase in

the proportion of adult females (14 to 24 to 31%). Subadult harvest declined from the pretreatment period (from 63 to 36%) but was consistent during the treatment period (35%) and was primarily composed of females (28 and 29%). Subadult cougars again dominated the harvest after harvest quotas were reduced, but subadult male composition was relatively higher than during pretreatment and treatment periods until the third year of recovery when the population returned to pretreatment levels. Annual harvest composition among adult males, adult females, and subadults differed significantly ($P<0.05$) from the pretreatment period through the first year post-treatment and was similar ($P\geq 0.66$) during the 3-year recovery phase.

We compared harvest records from Laramie Peak, the comparison population, to harvest records from the Snowy Range including the first 5 years of harvest (harvest levels below quota) in Laramie Peak and 2 years of harvest treatment and the first year post-treatment in the Snowy Range. During the 3-year period, harvest declined and pri-

Figure 1. Sex-age composition of cougar harvest (pie charts) in the Snowy Range, Wyoming, relative to population change through increased 1998–2003 and reduced 2003–2004 harvest levels (order of sex-age classes in bar graphs follows pie charts). Harvest quotas (ton and ratio) prior to 1999 represent harvest years 1990, 1997, and 1997–1998 combined. First column of the population estimate for spring 1998 was determined from mark-recapture data collected from capture and tracking efforts during winter 1997–1998; subsequent population estimates were derived using mark-recapture methods. Error bars represent 90% confidence intervals. Number of cougars known to be in the population each spring were 12, 13, 15, 19, 20, and 32, respectively.

mainly consisted of adult males initially, followed by adult females, and finally subadults in both populations (Figure 2). annual harvest composition was similar between populations ($P \geq 0.217$). Mean annual age of adult females declined following the first treatment year from 6–8 years old to 4–6 years old the second year in both populations. Unlike the Snowy Range, unrestricted harvests continued in Laramie Peak for the next 4 years, resulting in annual oscillations in harvest level and harvests of primarily subadults (Figure 2); adult females averaged 4.5 years of age during this period.

Characteristics of female cougar harvest

We noted that proportion of adults in the female harvest increased with harvest rate, ranging from 20% with a 22% harvest rate to 58% with a harvest rate of about 44% (Figure 1), but this relationship was not statistically significant ($r^2 = 0.10$, $P_{Y10} = 3.52$, $P = 0.14$). Sixteen adult and 19 subadult females were harvested (total harvest = 64) in the Snowy Range during the 2-year treatment and 4-year post-treatment periods. Of 8 marked adult females har-

vested, 1 were without young, 3 had young at the time, and we suspect the last female may have had young when harvested because we had seen kitten tracks with her 2 months earlier. All harvested females with young were taken during the treatment period (50% harvest rate).

Discussion

The Snowy Range cougar population recovered in numbers after 2 years of intensive harvest (>44% of independent cougars) followed by 3 years of light harvest (<18% of independent cougars). Recovery of the population was facilitated by immigration of males and recruitment of females from within the population as found in other recovering cougar populations (Lindzey et al. 1992, Logan and Swenar 2001). Composition of the harvest from pretreatment through the 2 years of heavy harvest supported our predictions based on predicted relative vulnerability of the various sex and age classes. The most vulnerable classes were harvested until their reduced abundance in the population

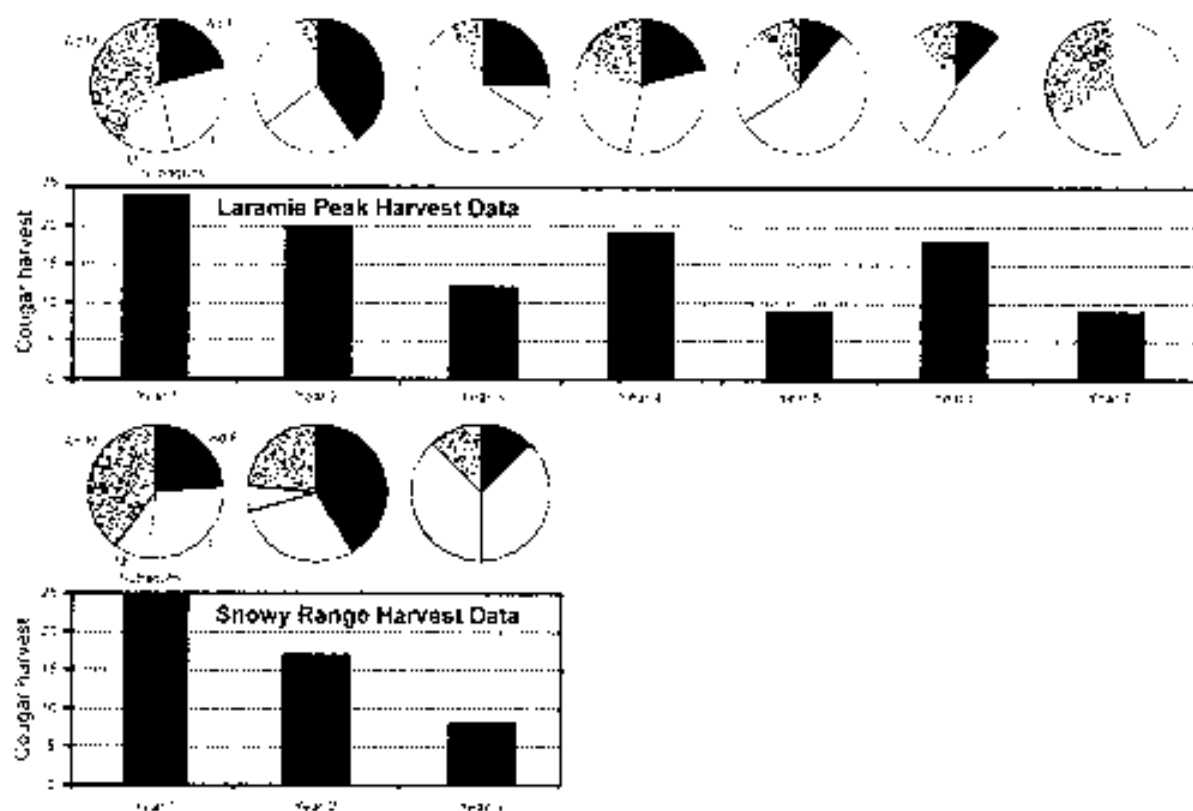

Figure 2. Cougar sex and age harvests during intensive treatment and post-treatment periods in Laramie Peak and the Snowy Range. Sex and age composition of the harvest is shown in the pie charts above the bar charts. Note that the composition of the harvest varies among the treatment and post-treatment periods. Sex-specific harvest rates are shown in the pie charts.

exposed the next most vulnerable class, terminating in a harvest dominated by adult females (Figure 1). The increase in adult females in the harvests coincided with a decrease in size of this hunted population, suggesting that proportion of adult females in harvests may be a useful indicator of trends in other hunted cougar populations. The similarity of composition trends in the Snowy Range and Laramie Peak populations during the initial years of intensive harvest suggests that the intensive harvest in the Laramie Peak population had achieved its goal of reducing population size in this area. Decline in average age of harvested females in both populations further suggested that harvests had similar effects on the 2 populations.

While factors other than composition of hunted cougar populations (e.g., weather patterns, changes in legal access) can influence harvest level, none should result in adult females dominating the harvest if they are not proportionately the most abundant sex or age class present in the population. Experienced cougar hunters often can differentiate males and females from track size, presence of scrapes, or body characteristics if the cougar is seen, but selective hunters tend to harvest males. Further, our experience suggests that hunters tend to be most selective when competition for available cougars is low. When demand exceeds harvest quotas, competition among hunters appears to result in less-selective hunting, and harvest should reflect the relative abundance or vulnerability of sex and age classes. Snow conditions also can affect hunting success (>90% of cougars harvested in Wyoming are hunted using hounds and most require snow cover), but this should influence harvest rate, not the relative vulnerability of the sex and age classes. Access, influenced by weather events or land-ownership patterns, can create ephemeral or more permanent refuges within cougar management areas. In these situations harvests may be maintained by adjacent, unavailable adult females providing young females for the harvest (e.g., Figure 2). We identified areas of suitable cougar habitat in the Laramie Peak area that received no cougar harvest and apparently were functioning as refuges. The similar abundance of subadult females in the pretreatment Snowy Range harvest and post-treatment harvests from Laramie Peak illustrates the contribution of refuges to maintaining harvests and underscores the need to monitor harvest composition over a number of years before drawing inferences about trend in the pop-

ulation from harvest composition. Subadult females in the pretreatment Snowy Range harvest reflected their relative abundance and vulnerability to harvest, while their dominance in later harvests from Laramie Peak apparently reflected their abundance in the portion of the area accessible to hunters. Examination of composition of earlier harvests should help identify whether the harvest reflects a lightly hunted population or one that has been reduced with harvests being supported by young produced by adjacent, unavailable adult females. Prior harvests in the Laramie Peak area were composed of progressively more adult females, suggesting the population had been reduced in size.

Management implications

Cougar managers typically have used harvest level and occasionally sub-quotas typically aimed at protecting females to achieve population objectives, although both imply knowledge of population size. While observations suggest that cougar populations can sustain harvest rates of up to 20–30% (Ashman et al. 1983, Ross and Jalkotzy 1992), the effect of harvests on populations will differ depending on sex and age of cougars removed. Harvest of males, the cohort most easily replaced by immigration, and subadult females, which can be quickly replaced by female young produced in the population, will have less impact on the population than harvest of adult females, which are more difficult to replace. Adult females that die are most often replaced by the population's female progeny and less often by immigrating subadults because most female progeny are philopatric (Lindzey et al. 1989,

Duggin Wroe's dog, Luna, corners male cougar number 610. Photo by Hall Sawyer.

Anderson et al. 1992, Logan and Sweeney 2001).

Monitoring levels of adult females in cougar harvests to index the effect the harvest is having on the population is intuitive. Sensitivity analyses by Martorello and Beausoleil (2003) suggest that cougar populations are most sensitive to survival of this sex and age class. Adult females provide the resiliency in a population that allows it to respond to loss of members. This approach will work well in an adaptive management framework, where harvest composition goals are set to achieve specific population objectives. Hunting programs can simply be modified until harvest composition indicates that desired population and recreation objectives are being met. The proportion of adult females in the Snowy Range harvest when the more vulnerable sex and age classes had been removed and the population was beginning to decline was about 25%, while the population appeared to sustain a harvest composed of 10–15% adult females (Figure 1). The 25% estimate came from a single experiment and should be used with caution in other programs because cougar populations more isolated than the Snowy Range or that contain more refuge areas may respond differently to similar harvest rates of adult females. Also, because harvest from a single management area in a single year may be too small to support inferences, and harvest level may vary because of weather events, combining years or adjacent management areas for analyses may be appropriate.

Acknowledgments. The Wyoming Game and Fish Department, Wyoming Animal Damage Management Board, and the Pope and Young Club funded this project. We thank D. Wroe, T. Barkhurst, S. Keller, and J. Talbot for cougar captures. Field assistance from J. Sherwood, H. Critchshank, L. Johnson, H. Sawyer, T. Chapman, R. Grogan, S. Rothmeyer, J. Koloski, and M. Hooker was appreciated. Thanks to D. France of France Flying Service, Rawlins, WY for aerial telemetry. Wyoming Game and Fish Department personnel from the Laramie Region and the Trophy Game Section were helpful throughout the project. This project would not have been possible without cooperation of the landowners surrounding the Snowy Range. Suggestions by C. L. Hayes and G. P. Keister improved the manuscript. Capture protocols were reviewed and approved by the University of Wyoming Animal Care and Use Committee (form No. A-321601).

Non-Invasive DNA-Based Black Bear Density Estimates in Colorado – 2009.

Jerry A. Apker, Paul Lukacs, John Broderick, Brian Dreher, Julie Mao, Allen Vitt

ABSTRACT We estimated black bear (*Ursus americanus*) density in two survey areas in Colorado. The southeast survey area (SESA) (575 km²) is located northwest of Trinidad, Colorado, and the northwest survey area (NWSA) (500 km²) is located southwest of Glenwood Springs, Colorado. Each survey area represents high quality black bear habitat. Surveys were conducted from late June through early August of 2009. Scent baits were used to attract bears to hair snag stations and natural rub trees adapted for hair snagging were used to non-invasively collect hair samples from which DNA could be extracted and genetically analyzed. Tissue samples from black bear mortalities and also from conflict bears handled in the vicinity of the survey areas were also a source of DNA for analysis. All samples of adequate quality were genotyped using 7 microsatellite loci and gender identified using the ZFX/ZFY gender marker method to identify unique individuals within the survey areas. We used several different mark-recapture analysis methods and applied assumed home range data from Idaho and New Mexico to calculate a range of possible densities. Applying the most robust mark-recapture methods, our analysis suggests that there are 45-50 bears/100 km² in the NWSA. In the SESA our analysis indicates 44-85 bears/100 km². Analysis challenges and key assumptions are discussed.

We conducted surveys to non-invasively collect DNA samples of black bears in two survey areas of Colorado. Both survey areas were selected because they are considered high quality black bear habitat and are in relatively close proximity to high human-bear conflict areas. One survey area was located near the Spanish Peaks, northwest of Trinidad (SESA) (Fig. 1) in Game Management Unit (GMU) 85, Data Analysis Unit (DAU) B-9. The other was near Divide Creek, southwest of Glenwood Springs (NWSA) (Fig. 2) in GMUs 42 and 43, DAUs B-11 and B-17. The SESA was 575 km² and the NWSA was 500 km² in size.

With minor modification survey protocols followed those described by Kendall (K. Kendall, USGS, personal comm. 2009) for research being conducted on grizzly (*Ursus arctos*) and black bears in northwestern Montana and previously by Mowat and Strobeck (2000) and Woods et al. (1999). We modified the survey protocols by using a smaller grid area of 25 km² (~9.5 square miles per grid) in order to accommodate a survey focused solely on black bears which have smaller home range areas than grizzlies. The smaller grid area provides increased opportunity for all bears within the survey area to have opportunity to encounter one or more snag stations. The survey areas ultimately were configured to their final shape and size in order to include bear habitat typical of the high quality habitat in the DAUs they are located and also to avoid human development (or potential human conflicts).

Vegetation types were grouped into broad categories and differed between the two survey areas (Table 1). Ponderosa pine and ponderosa affiliations with gambel oak or aspen was a significant component of plant communities in the SESA, but absent from the NWSA. Oakbrush and serviceberry were avoided

Table 1. Vegetation composition in survey areas based on CDOW GIS Basinwide layers, in broad categories.

Vegetation types	NWSA % composition	SESA % composition
Aspen dominant	40%	4%
Conifer (not ponderosa pine)	21%	21%
Ponderosa Pine	-	33%
Conifer/Aspen Mix	10%	6%
Gambel Oak	10%	17%
Berry/Mesic Mtn. Shrub	8%	-
Sagebrush	3%	-
Pinyon-Juniper Mix	1%	6%
Dryland/Irrigated Agri.	<1%	2%
Alpine/Subalpine (grass, forb, or shrub)	2%	1%
Riparian	1%	1%
Other	4%	9%

and aspen stands or mixed aspen/conifer types were selected for when formulating the grid area in the NWSA. While oakbrush and serviceberry are important black bear habitat types in fall season, they were not deemed as important for a survey conducted in the summer on the NWSA. In contrast, the SESA included oakbrush habitats (although serviceberry was not present in the SESA). The SESA also included more open meadow grassland areas and dryland and irrigated agriculture lands which were not found in the NWSA.

We collected hair from late June through early August. Snag stations were baited mainly with decomposed, liquefied fish (mung) soaked burlap and drizzled on logs, Anise oil soaked burlap strips, decomposed deer roadkill-soaked burlap strips. Some stations were baited with portions of road kill deer or elk. Hair collections occurred every 5-7 days on average (\bar{x} = 6 days, range 2-10 days) for up to 9 repeated collection sessions.

We collected tissue or hair samples from black bears handled due to human conflicts during the course of summer and fall. We also collected tissue samples from other bear mortalities such as road kills, second strike bear, or hunter harvest documented by the Division of Wildlife (DOW). We submitted these additional samples from GMUs within or surrounding the survey area for genetic analyses. NW GMUs for these additional samples included 33, 34, 42, 43, 45, 47, 421, 444, 471, and 521. SE GMUs for these additional samples included 83, 861, 84, 85, 851, and 140.

Results

A total of 1,103 snagged hair samples were submitted to the lab for analysis; 457 from the NWSA and 646 from the SESA. An additional 259 samples (161 from NW GMUs, 98 from SE GMUs) were submitted from harvest mortality, non-harvest mortality, or euthanized conflict bear; these are called “known bear” samples. Wildlife Genetics International conducted the genetic analysis under the direction of Dr. David Paetkau, president and geneticist. We have attached the genetic analysis report to this report. Laboratory protocols exceeded DOW specified quality controls and Dr. Paetkau independently, and at no charge to DOW, took additional steps to conduct more detailed analyses and to safeguard against false identifications of unique individuals.

The genetic analysis resulted in identification of 117 unique bears in the NWSA and 149 unique bears in the SESA. We documented a surprisingly low number of recapture events (Table 2). We reconstructed the capture histories for all identified individuals.

Table 2. Summarized capture history by site and ‘x’ week.

Number of times detected	NWSA		SESA	
	Individuals	% of total	Individuals	% of total
1	82	70%	113	75%
2	19	16%	18	12%
3	13	11%	10	7%
4	2	2%	4	3%
5	0	-	4	3%
6	1	1%	0	-
Total	117		149	
Recaptured in Harvest or other	6	-	4	-

In general, the frequency of capturing new individuals declined over time (Table 3). Declining numbers of new individuals is expected in capture-recapture sampling, but other factors may have contributed to the decline. Bears may become attenuated to the bait material or bears may be beginning hyperphagic movement to lower elevation mast production areas. Bait attenuation might result when bears detected no novel scents and having previously explored baits used at one or more snag stations were no longer driven to investigate the scent further. We attempted to mitigate bait attenuation by using different bait material at different snag stations over time. Although, not all snag stations had different baits over the course of the survey.

Table 3. Summary of captures of new female and total individuals by week.

Week #	NWSA				SESA			
	Date Start	Date End	New Female N	New Total N	Date Start	Date End	New Female N	New Total N
0	6-9	6-12	5	9				-
1	6-16	6-18	9	23	6-22	6-26	18	31
2	6-23	6-27	12	22	6-29	7-3	8	25
3	6-26	7-1	9	16	7-6	7-10	9	20
4	7-2	7-8	3	8	7-13	7-17	5	13
5	7-9	7-14	7	9	7-20	7-24	9	17
6	7-15	7-22	5	14	7-27	7-31	10	17
7	7-22	7-28	3	10	8-3	8-7	6	13
8	7-28	7-31	3	6	8-10	8-14	4	13
Sum			56	117			69	149

Movements by bears to lower elevation mast production areas would be expected later in the summer to early fall as bears entered hyperphagia. This could result in less frequent detection of new bears as they moved out of the survey area in later survey collection sessions. This should have been most notable in the NWSA since its grid layout avoided substantial oakbrush/serviceberry vegetation complexes, although it could have been offset by the earlier end date of the NWSA survey. While the NWSA survey efforts were concluded prior to the expected time in which bears would enter hyperphagia, it might be possible that movements toward lower elevations occurred earlier than we predicted.

Density

We analyzed the encounter data using three different mark-recapture analysis methods (Table 4); spatially-explicit mark-recapture (Bochers and Efford 2008), maximum likelihood mark-recapture (Otis et al. 1978), and a jackknife mark-recapture (Burnham and Overton 1979).

Spatially explicit method. This method uses the distance between captures to estimate the average center of activity and area used by a bear. With sufficient recapture events this method would provide a strong representation of the size area that bears are moving within during our sampling time frame. The paucity of recaptures we have to work with severely weakens this analysis. Because there are so few recapture events we are not confident that they are representative of the actual area of use by bears in either survey location. Although this estimation method suffers from the low number of recaptures in 2009 it can be applied across multiple years which increases sample sizes and increases the power of the analysis. This estimation method results in density estimates of 47 bears/100 km² in the NWSA and 44 bears/100 km² in the SESA.

The following two estimation methods attempt to account for the effect of enticing bears that may be on the periphery of the survey area into snag stations. In any survey of this nature there will be some individuals whose home areas overlap the outer boundary of the survey area. Presumably, these bears may be enticed to hair snag stations by the scent baits. Since their home areas extend beyond the outer edge of the survey area, there must be some accounting for the larger geographic area of impact when calculating an estimated density. The mechanism for doing this is to apply an estimated home area at each snag station point. The estimated home area is derived from projecting an area with ½ the radius of an assumed home area. The outer perimeter of this projection is then used to compute an estimation of the amount of area actually surveyed. The estimated population size from the mark-recapture analysis is then divided by the estimated survey area to arrive at the density.

The assumed home area values used for our analysis were estimates from Idaho research (Beecham and Rohlman 1994) and the mean annual primary home area found in the northern study area (NSA) in New Mexico (Costello et al. 2001). In both cases we used home ranges estimated for males and females. In the Idaho research, home areas were presented in a range so we applied a small and large home area size to yield a range of density here as well. The primary home area in New Mexico doesn't include the long distance movements that bears occasionally embark upon, but subsequently return from (Costello et al. 2001, Baruch-Mordo personal comm. 2009). Ultimately we selected Idaho and New Mexico home area values due to the similarity in our raw density (minimum individuals per total grid area) and Idaho density results, and similarity of New Mexico NSA habitat to Colorado survey area habitats.

Home area data from Colorado studies were not used for several reasons; the Black Mesa study (Beck 1991) estimated annual ranges from relatively infrequent VHF locations per individual bear and consequently computed an extremely wide range of home area sizes (although the mean values fell within the range of values we applied). Data from the more recent Roaring Fork valley investigations were not used because all tracked bears were captured within towns and represent potentially biased home areas as "conflict" bears. In addition the principle investigator was out of the country and unavailable to update home area sizes reported from 2007 data.

Maximum likelihood method. This method estimates the number of bears available to be detected in each survey. We then applied the assumed home area values to the estimated population size to calculate density. This method assumes that there is no difference in detection probability among individuals (except by sex which can be analyzed separately). This assumption is known to result in estimates biased low when compared to known densities. This analysis method yields an estimated density range of 28-32 bears/100 km² in the NWSA and 54-59 bears/100 km² in the SESA.

Jackknife method. This method applies home areas in the same manner as the maximum likelihood method. This method does assume that there is variation in the detection probability among individual bears, but doesn't presume any specific cause for the variation. This assumption seems reasonable. This analysis method results in an estimated density range of 45-50 bears/100 km² in the NWSA and 78-85 bears/100 km² in the SESA.

Table 4. Estimated black bear densities derived from hair snag mark recapture analysis. Results are from three methods; spatially explicit model, maximum likelihood model, and the jackknife model. The maximum likelihood and jackknife models apply assumed home range areas from New Mexico, northern study area (Costello et al. 2001) and Idaho (Beecham and Rohlman 1994). The Idaho home areas presented a range of values, therefore we applied a small home area value and a large home area value in our analyses.

Spatially Explicit Capture-Recapture					
Combined Gender Density		Bears/ha	SE	Bears/sq. mile	SE

Ideally at least two of the methods would produce similar estimates and thus we could have confidence in selecting results with most relevance for management. Unfortunately, substantial differences exist between the estimates for each method. Future results will help us draw more meaningful conclusions and inferences. In the interim, managers should consider that our results may have potential biases in capture probability between age classes and genders and could also be influenced by our assumed home area sizes. Although preliminary and considering the various assumptions in the different methods we place most confidence in the estimates produced by the spatially explicit and jackknife methods which yield densities of between 45-50 bears/100 km² in the NWSA and between 44-85 bears/100 km² in the SESA.

In order to place our results into context, we examined black bear density estimates from certain studies in different States and Provinces, representing different habitat types (Table 5). Although there is little doubt that the method of density estimation along with size of the study area plays a role in density estimates, we

attempted to minimize disparity by selecting reports from, in most cases, mark-recapture surveys. However, three are derived from minimum individual animal reconstructions (Colorado – Beck 1991, Utah – UDWR 2000, and Colorado – Baldwin and Bender 2007). We also excluded extremely small study areas with the exception of island habitats (Washington – Lindzey 1977 and Wisconsin – Belant et al. 2005), where populations would be closed and allow for more accurate enumeration. We included the Nevada – Tahoe Basin urban estimate (Beckmann and Berger 22003) due to the extreme influence of a highly rich food source. In general, black bear densities are greater in areas of greater quality and abundant forage.

Table 5. Reported black bear densities from research, analysis, or management reports in diverse locations and habitat types. Bullet •, indicates results of this study.

Location	Source	Per 100 km²
Washington	Lindzey 1977	112 – 149

Wyoming	Grogan and Lindzey 1999	2.1 – 3.0
Colorado - RMNP	Baldwin and Bender 2007	1.35

Application of this particular survey methodology (scent bait hair snag station) commonly results in a bias against small black bears (D. Moody, WY G&F, personal comm. 2009, K. Kendall, USGS personal comm. 2009). Given that the first year results show relatively high bear densities, bear home range areas in our survey locations may be smaller or more overlapping than we first considered and consequently we potentially missed bears because snag stations didn't occur in some bear home areas within the overall survey area. The hair collection methodology definitely misses most cubs, due to both their size and behavior. To a lesser extent the negative bias extends to sub-adults and females but the extent of bias isn't known.

A second consideration for interpreting the results is the influence of our assumed home area. We used assumed home areas in two of the mark recapture analyses in order to consider the potential "impact area" from which we were actually surveying bears. The home area values we used were annual home areas. We presume that these home areas are likely to be larger than the area that bears are using in the relatively short period that hair is being collected. We offset this potential error somewhat by including opportunity for recapture to include fall hunter harvest periods when bears will have had opportunity to use more expansive portions of their home areas.

Another consideration is that cementum age data on large numbers of harvested bears in Colorado, statewide, as well as in the vicinity of these two survey areas shows a relatively young mean and median age structure for

Colorado bear populations. Cementum age structure derived from hunter harvest is almost always biased younger than the actual population. Yet comparing Colorado's harvest age composition results to hunter harvest results in other states has indicated that Colorado appears to have a younger average age at harvest. If this is reflective of the actual population then a larger than expected portion of bears on both survey areas may be highly mobile animals, yet to settle into an established home area. Consequently, the potential "impact area" may be much larger than that represented by even large home areas and the resulting density of bears would be lower than our results show. This could also explain the relatively low number of recapture events during hair snag collection sessions. It does not, however, explain why there were relatively few hair snag bears 'recaptured' in hunter harvest.

Gender

Hair snare captures and known bear captures were slightly male biased (53% and 56% respectively). The "known bear" group of samples is derived mostly from hunter harvest. Genetic gender identification of this group closely matches the identification of gender reported for hunter harvest in the 3 DAUs in which the survey areas (56.7% male). In fact, out of 256 unique genotypes identified from the known bear captures group only 4 bears identified as male at the mandatory check were, based on genetic analysis, found to be females.

The small difference between mortality based samples (56%) and hair snag population based samples (53%) could be due to normal variation in sample collection or could be attributed to a slight tendency of hunters to select for larger bears which tend to be males more frequently than females. Likewise, the slight male bias in the hair snag sample may be due to normal variation in sample collection or could be due to the previously discussed bias against smaller bears, which tend to be females and young bears.

Conclusion

Our results are among the highest black bear densities reported in the Rocky Mountains, but are not inconsistent with other densities derived from mark-recapture methods in most other highly productive mast producing habitats. Although the small recapture sample sizes, especially the independent known bear (mortality based recaptures), influence confidence in our computed densities, future replication of the surveys will increase sample size and power and therefore increase the confidence of our estimates.

With that in mind, we have replicated both survey areas in 2010 and have begun sending samples to the laboratory for analysis. It is our plan that the NWSA is concluded and a new survey site will be selected and should be conducted for two years. The SESA is an area in a DAU in which some experimental management is planned. Therefore, we propose to continue with surveys in this area through 2013 to test if bear population trend can be detected. After 2013 we propose to close the SESA and move to another site.

We suggest that at least two survey areas should be continuously operated in Colorado until representative densities derived from two consecutive years of survey data are obtained for each black bear DAU. Conducting surveys in this manner will support and bolster black bear DAU plan development which has begun this year. Results from surveys can be applied to habitat and population models and ongoing monitoring in experimental management strategies.

Re: WGI project g0805 Colorado BB

Dear Sirs:

I have enclosed genetic results for 1,362 black bear hair and extracted DNA samples that we received from you on January 21st, 2010. The results are presented in the attached MS Excel workbook in which one spreadsheet lists field, extraction and genetic data for each sample, while a second sheet summarizes information by individual. The following notes should provide the information needed to understand and defend this project, but feel free to contact us for further detail on any aspect of this project.

Sample Classification Summary

Of the 259 samples from known bears, 256 produced complete genotypes suitable for individual identification, including all 210 of your DNA extracts. The 1,103 hair samples from snares were classified as follows:

- Xspecies* (0%): 5 samples that did not look like bear hair
- Xinadequate* (22%): 241 samples that lacked suitable material for extraction
- Xmixed* (1%): 12 samples that appeared to contain DNA from > 1 bear
- Xbomb* (13%): 139 samples that failed during genetic analysis
- sample* (64%): 706 samples with complete genotypes for 7 microsatellite markers (plus gender) that were assigned individual ID

The 706 good snare samples were assigned to 266 individuals, while the 256 successful 'known' samples were assigned to 256 individuals.

Database Issues

We noted the following discrepancies between database records and information on sample envelopes:

Samples NW0512 – NW0519 show a trap site of 04_01 in your spreadsheet versus trap site 09 on the envelopes.

Sample SE0312 shows a trap site of SE15A-4 in your spreadsheet versus trap site 21A on the envelope.

The following discrepancies were noted between the collection dates indicated in your spreadsheet and those on the sample envelopes:

Sample ID	Date in Spreadsheet	Date on Envelope
SE0490 – SE0500	8/6/2009	7/30/2009
SE0510 – SE0514	8/6/2009	7/30/2009
SE0538	8/3/2009	8/10/2009
NW0668	7/13/2009	7/12/2009
985121006936833	7/5/2009	7/7/2009
4452666771	8/29/2009	12/18/2009
NW0571 & NW0572	6/27/2009	6/26/2009
985121009462869	9/9/2009	9/11/2009
985121009094047	8/29/2009	12/18/2009

The following discrepancies were noted between the barb numbers indicated in your spreadsheet and those on the sample envelopes:

Sample ID	Barb # in Spreadsheet	Barb # on Envelope
SE0352	122	120
SE0607	73	74
SE0608	74	73
NW0626	132	134
NW0671	48	47

DNA Extraction

In dialogue with you, and with reference to preliminary results, we decided to exclude samples from the extraction process if they contained no guard hairs with roots and < 5 underfur (*Xinadequate*) or if their appearance was inconsistent with that of bear hair (*Xspecies*; mostly coarse ungulate hair or banded hair). We noted a disproportionate number of inadequate samples from the SE region (32%), as compared to the NW region (7%).

DNA was extracted using QIAGEN's DNeasy Tissue kits, and following the manufacturer's instructions (for details search <http://www.qiagen.com/>). We aimed to use 10 guard hair roots (see '#G' column) where available. When underfurs were used, the number recorded (see '#U' column) was an estimate because entire clumps of whole underfur were extracted rather than clipping individual roots. An estimate of the amount of the leftover hair (see 'Left' column) was made using three classes: no guard hairs (C); 1–4 guard hairs (B); and > 4 guard hairs (A).

Sample quality was very good, with a mean of 4.8 guard hairs per extracted sample. Many of the samples from known bears had shorter hairs that we typically see, although this did not appear to affect results. If possible, however, we would prefer longer hairs, as these tend to have larger roots and are easier to work with. Alternatively, a piece of footpad the size of a lentil is the best sample material from dead bears, both for ease of handling and data quality.

Marker Selection

Marker selection turned out to be more involved than we envisioned, as we struggled to find markers with the 75% to 80% heterozygosity that we expect in large black bear populations. We initially screened 12 markers that had worked well in previous black bears projects from Utah, Idaho, Texas and Wyoming. These markers were tested on 30 known bears, after which we identified 6 markers (*G10J*, *G10L*, *G10B*, *G1D*, *G10H*, and *G10M*) with mean $H_E = 0.76$ to use for analysis of individual identity. We decided to add a gender marker to this 6-locus system, providing a further reduction in match probability of $\sim 50\%$.

After analyzing ~ 200 samples we became concerned that there were more pairs of highly similar genotypes than expected, suggesting a higher than anticipated match probability. We also began to fully appreciate the large number of individuals that you had sampled, which creates a challenge since the number of false matches between individuals scales with the square of this number. We

therefore tested another 8 microsatellite markers on 29 or 30 individuals, and identified a 7th marker (*GIA*) to use in the analysis of individual identity. This marker had the largest observed number of alleles of the 14 candidate markers (20 minus the 6 already in use) based our sample at the time of 29–30 individuals. The remainder of the analysis of individual identity was therefore conducted with 8 markers, including 7 microsatellites and a gender marker.

Unfortunately, with the benefit of hindsight (Table 1) we can see that *GIA* was not as variable as our original marker selection data had suggested, and that it would have been better to use *G10U* as the 8th marker. Despite the large number of alleles at *GIA*, allele 192 occurs at such high frequency (> 70% in the NW study area) that the marker contributes little to individual identification. I recommend that future projects in this region replace *GIA* with *G10U*, and continue to use 7 microsatellites, plus a gender marker.

Table 1. Summary of marker variability. The first 7 markers, and a gender marker, were run on every sample for the purpose of individual identification. *G10U* was subsequently run on 1 sample per individual to further differentiate pairs whose genotypes were so similar as to be candidates for genotyping error.

Locus	<i>N</i>	<i>H_E</i>	<i>H_O</i>	<i>A</i>

Microsatellite Analysis

While the marker selection was not straightforward, the analysis of individual identity went smoothly once the markers were selected. This analysis started with a first pass of all 8 markers (including gender). After first pass, we culled 10 mixed samples (*Xmixed*) and 119 samples that had produced high-confidence genotype scores¹ for < 4 of 8 markers. This culling step is central to the efficiency and accuracy of our process, eliminating the samples with the lowest success rate and the highest rate of genotyping error (Paetkau 2003).

¹ We use a combination of objective (peak height) and subjective (appearance) criteria to classify genotype scores. Low-confidence scores are identified by removing the leading digit from the allele score, and should be treated as equivalent to missing data.

The first pass was followed by a cleanup phase in which we re-analyzed data points that were weak or difficult to read the first time. In some cases multiple rounds of re-analysis were used to confirm weak data points. Another 21 samples were excluded following cleanup, but the remaining 962 samples had complete, high-confidence scores for the 8 markers that we were analyzing.

The last phase of analysis was error-checking, following our published protocol of selective data re-analysis (Paetkau 2003). Through a combination of reviewing the original results for data entry errors, and re-analyzing obvious candidates for amplification error, we found 12 errors in the new data. We normally encounter errors in about 2–3% of remotely collected hair samples (Paetkau 2003), so the number of errors detected in this project was below average at ~ 1.25%. Rates of amplification error vary with sample quality, suggesting higher than average sample quality in the current project.

After correcting these 12 errors, there were 4 1MM-pairs (pairs that matched at 7 of 8 markers) and 24 2MM-pairs remaining in the file, as well as 6 3MM-pairs that fit the pattern expected of ‘allelic dropout’ (ADO; the only type of error that is expected to affect 3 markers in a single sample). With this total of 34 pairs that were candidates for error-checking, we decided to analyze *G10U* on each pair (1 sample per genotype) to reduce the number of similar pairs prior to the formal process of confirmation through re-analysis.

After adding the *G10U* results there were 2 1MM-pairs, 5 2MM-pairs, and 2 ADO-style 3MM-pairs left in the file, each of which was then confirmed by re-analyzing the mismatching markers (twice for the 1MM-pairs). Extensive testing with blind control samples has shown that this protocol effectively prevents the identification of false individuals through genotyping error (Kendall *et al.* 2009).

Notes on the Gender Analysis

We originally indicated that the amelogenin marker would be used for gender analysis, and we started the analysis using that marker. However, the decision to add *G1A* to the analysis created a size overlap conflict with amelogenin, prompting us to switch to a newer ZFX/ZFY gender marker. This marker is functionally equivalent to amelogenin, using a single pair of primers to amplify a segment of DNA that occurs on the ‘pseudoautosomal’ portion of the sex chromosomes, but with different lengths on the X- and Y-chromosomes.

Some of your samples arrived with 'known' gender from the field, but we included these samples in the gender analysis since we were already setup with an 8-locus marker system for the rest of the project. There were 4 cases where successful known samples were identified as male in your spreadsheet but then produced female gender results. We analyzed each of these samples at least twice for gender, including at least one analysis with the amelogenin marker. Given the reproducibility of the results, and the concordance between markers, we believe that these 4 animals are indeed female. Gender results for these bears are highlighted in yellow in the results file.

A final note on the gender results is that they come with an expected error rate of ~ 0.001 unless they have been replicated. When more than one sample is identified per individual, then the entire genotype has been replicated between samples. A subset of samples (~ 1 in 30) were also replicated by being re-run as positive control samples. However, in many cases there was only 1 sample identified from a given individual, and there was no field data to confirm the gender, and in such cases there is no method short of wholesale data replication for detecting the approximately 1 in 1000 animals with inaccurate gender data.

Notes on the Success Rate

Of the 706 successful snare samples, 274 were extracted from samples that did not meet the original quality threshold of 3 guard hairs. Success rate, expressed as the proportion of extracted samples that were analyzed successfully, was higher than we typically see, at 80% for the SE region, 85% for the NW region, and 99% for known bears. We expect remotely snared samples to have a lower success rate than samples from bears that have been physically handled, but I was interested in the difference between study areas, and so looked at that in more detail.

While there was an obvious difference between study areas in terms of extraction rate, among the samples that were collected in June and July the success rate for the SE study area was only 2–3% lower than for the NW study area. In both areas the extraction rate and the success rate were lower in July than in June. Where the study areas differed more significantly was that August collections were only made in the SE, and the success rate for August was substantially lower than for either June or July. This decline in sample quality as the season advances has been noted in other studies, and we presume that it relates to the ease with which hair can be pulled at different times of year. In studies that continue into the fall, and even into winter in places like Florida, sample quality continues to decline until spring.

Identification of Individuals

Once the genotypes were completed and checked for errors, we defined individuals for each unique genotype, taking ID numbers from the first sample to be assigned to a given individual. This information is cross-referenced in the “Individual” column of the “Samples” worksheet, and the “List of Samples” column of the “Individuals” worksheet.

The 706 hair snare samples with good genotypes were assigned to 266 individuals (117 NW, 149 SE), with no individuals caught in both study areas.

Unsurprisingly, the 256 known samples were assigned to 256 different bears, including 10 ‘recaptures’ of bears identified from hair snare samples. In each case where a snared bear was matched to a known bear, the gender results were the same, and the snare capture event preceded the physical ‘capture’ event. Both the hair snare captures and the known bears were slightly male-biased (53% and 56% male, respectively).

Marker Power

The 6-locus marker system that we started the project with (the first 6 rows of Table 1) have a respectable H_E of 0.77, in keeping with our recommendation for 6-locus marker systems (Paetkau 2003). Each individual that we identified in this project had a unique genotype for these 6 markers, so the addition of a gender marker and *GIA* to the analysis had no practical influence on the individual identifications.

Calculated match probabilities vary by orders of magnitude depending on what assumptions are made about the degree of relatedness among the individuals sampled. For example, in the current file the sibling match probability for the 7 microsatellite markers at which all samples were typed was 2×10^{-3} whereas the match probability for unrelated individuals was 1×10^{-7} (both of these values should be multiplied by approximately 0.5, which is the match probability for gender, independent of degree of relatedness). The disparity between these values renders them unhelpful for assessing the actual risk that we sampled any pair of individuals with the same 8-locus genotype.

An alternative to calculated match probabilities is to extrapolate from an observed mismatch distribution (Paetkau 2003). Experience with data from known individuals has shown that this approach provides a more precise estimate of the risk of false matches. For example, had we analyzed the 256 known bears in this

dataset using just the first 4 markers in Table 1 — reducing the number of markers to the point where some false matches will occur — extrapolation from the observed mismatch distribution would have provided a reasonable prediction of the number of false matches (Fig. 1).

While each of the 256 ‘known’ bears had a unique 8-locus genotype, we would like an estimate of the risk of false matches in the rest of the dataset, either between pairs of snared bears, or between snared bears and known bears. For this exploration I used the 7 markers that I am recommending for continued use, allowing us to confirm that those 7 markers have an appropriately low match probability. The 7-locus mismatch distribution included 5 1MM-pairs (Fig. 2), which is enough to convince us that an 8th marker is called for, but not so many as to call into question the current results.

My conclusion is that the marker system used in this project left little chance for false matches between individuals, but I encourage you to look for evidence of errors as you compare the genetic results to your field data. For example, if we have placed an animal at implausibly distant points within a short period of time, the samples in question should be analyzed at additional markers to confirm the match.

Fig. 1. Distribution of genotype similarity for 256 known bears using data from just 4 markers. This example illustrates how extrapolation from an observed mismatch distribution can accurately predict the number of pairs of animals with identical genotypes (3 in this example).

Fig. 2. Actual mismatch distribution for 512 individuals in the attached results file, based on the 7 markers (including gender) that we recommend to continue using (i.e. without *GIA*). Extrapolation suggests < 1 pair of individuals with identical genotypes were sampled. Adding *G10U* to future analyses would further reduce the match probability.

Population Clustering

I realize that we were unlikely to have sampled any grizzly bears, or immigrants from genetically distinctive populations, but it is always worthwhile to check a dataset like this in a clustering program to see if any individuals stand out for any reason (e.g. genotyping error). I was also interested in the distinctiveness of your two study areas, although I don't know their locations. I therefore performed a quick clustering analysis in the program Genetix, which performs a principle components-style treatment on individual genotypes. Out of personal interest, I included reference data from a similar project in Utah.

While the clusters produced for the SE and NW study areas were not superimposed, as would be expected if they were genetically homogeneous, the degree of differentiation between areas appeared slight (Fig. 3). There was one particular outlier that I looked at in detail, including reviewing genotyping runs, but this appeared to be a simple case of an individual with a rare genotype, as are often encountered when clustering analysis is based on so few markers.

Fig. 3. Results from the first two dimensions of a factorial correspondence analysis (program Genetix) based on 6-locus microsatellite data from NW (white), SE (grey), and 'known' (blue) study groups, as well as comparative data from an unknown population in Utah. Data for *GIA* were not available from Utah, so this marker was not included in the analysis. I could find no explanation for the outlier at bottom right, other than it had some rare alleles in its genotype; an analysis based on more markers would be required to conduct a serious investigation of individual origins.

Various and Sundries

It is my intention to communicate these documents in electronic form only, but I'd be happy to send hardcopies through the post if you need them. An invoice for US \$43,550 accompanies these results, with unit prices taken from the contract (including the \$5 discount for samples that you extracted). We did not charge you for a customs invoice that we received because you declared a commercial value of \$200 on the shipment, but please enter a nominal value of \$1 on future shipments. Unless you tell me otherwise, I'll count on you to get the invoice to the appropriate desk for processing.

While there were unusual administrative demands associated with the lead up to this project, and unexpected complexities at the marker selection phase, the high sample quality, large sample size, and straightforward nature of the work alleviated any initial concerns about the financial viability of the project. Now that we have dealt with many one-off complexities, any opportunity for involvement with your future studies would be more than welcome.

We understand that you would like any unused hair returned to you. Please let us know the contact name and address for where you would like the hair sent, as well as a courier account to which shipping charges can be billed. Note that we are also willing to archive your leftover materials under appropriate conditions for 5 years, as long as there is a prospect for continuing work; we often refer to such archived material when error-checking new data against old, or when adding data in the context of population genetics or parentage analysis.

Please keep us in mind when distributing reports relating to this work; we are always interested to learn more about the projects that we have worked on.

Thank you for your patronage, and please feel free to call with any questions or concerns.

Yours sincerely,

David Paetkau, Ph.D.
President

INTRODUCTION

The mountain lion (Felis concolor) is one of the most intriguing large game species in Nevada and the controversies surrounding this great cat have often become embroiled in a battle between fact and fiction, love and hate, and conservation and exploitation.

In its simplest interpretation the lion has been merely laying claim to the land it has freely roamed since the Pleistocene epoch. The recent invasion of its realm by the modern American and his livestock, followed by the bounty hunter, the fur hunter, and the sport hunter, contradicted that claim and resulted in a reduction of Nevada's mountain lion populations, as well as a conflict in ideologies among the people of the state. Hopefully, now, in a more enlightened period, we may, in some way, find a means of compromising the forces which have been working against the mountain lion's survival. In order to do this a basic understanding of the lion's life history is required so identified conflicts can be resolved or mitigated. If the myths are separated from the facts, and people are willing to try and resolve their differences, then a management plan which will provide for sustained mountain lion populations can be implemented.

In March 1972, the Nevada Department of Wildlife initiated a study of the mountain lion as a part of the Ruby-Butte deer project (Papez 1976) in eastern Nevada. The objective was to determine the status of lion populations within this highly valuable deer area and evaluate them in relation to deer populations. Within two years this objective was changed to: a) establish population estimates of mountain lions by mountain range or management area statewide, b) establish basic habitat requirements, 3) establish a harvest management program. From that period on, increased emphasis was placed upon lion capture and marking with the more sophisticated telemetry devices which were being manufactured. This program involved lion monitoring from both land and air and was instrumental in expanding our life history data base as well as providing an approach toward estimating the annual population status of key mountain ranges. The findings which resulted from this study were then utilized in formulating an approach toward estimating statewide lion populations.

In doing this, the Department was essentially moving toward the development and implementation of a Unit Harvest Management scheme. This management approach was a direct result of pressures arising from three distinct groups of people, all of whom had different interests:

1. The livestock industry which wanted stringent predator control.
2. The professional mountain lion guide who wanted the freedom of taking clients where he desired, with minimum restrictions in season length, harvest, or area of hunt.
3. The protectionist who basically wanted no harvest of the mountain lion.

The role of the Department of Wildlife was, therefore, one of attempting to develop a plan which satisfied most interests as well as meeting the legislative mandate of preserving viable mountain lion populations for the future. In the latter years of the study, while developing a Unit Management approach, Department personnel throughout the state were assigned to pertinent jobs in their local areas, the study areas, or both.

ACKNOWLEDGMENTS

Dave Ashman was the principal investigator assigned to the mountain lion study during most of its ten year duration. A rough draft, which was partially used in the preparation of this manuscript, was written by Dave prior to his resignation from the Department in 1982.

Personnel from the United States Fish and Wildlife Service cooperated in this study from its initiation by providing experienced lion hunters with trained hounds and much of the necessary equipment. The late Dick Hall, a U.S. Fish and Wildlife Service lion hunter in Nevada from 1936-79, unselfishly provided a vast storehouse of knowledge, time and experience during the first 7 years of the study. Jim Bahler and Richard Holcomb, also government lion hunters, provided able assistance in capturing lions during the last 3 years of study.

Many Department of Wildlife employees assisted in the field work, some of which was done under the most adverse winter conditions. A listing of them would include almost the entire Game Division staff and most of the Regional game personnel, all of whom willingly assisted in study design, equipment procurement, and endless hours of field work. Allan Flock, Jim Jeffress and Gregg Tanner provided help beyond the normal call of duty.

Dave Beatty of Telonics, Inc. was instrumental in designing and manufacturing the telemetry equipment which was used so successfully during the later years of the study. A phone call to Dave saved many a day when there were equipment crises.

Glen C. Christensen was responsible for data analysis, rewriting and editing of this manuscript. In doing so he drew freely upon the talents of George Tsukamoto, Mike Hess and Mike Wickersham of the Nevada Department of Wildlife and Harley Shaw of the Arizona Game and Fish Department.

DESCRIPTION OF THE STUDY AREAS

Location

The principle study areas were located in the Ruby Mountains (eastern Nevada) and in the Monitor Range (central Nevada). Additional, but less extensive work was conducted in the following ranges: Schell Creek, Cherry Creek-Egan, Spruce, White Pine, Toona, Maverick Springs, Snake, Jarbidge and Antelope-Fish Creek, all of them being grouped in Northeastern and Central Nevada (Figure 1).

RUBY MOUNTAINS--The Ruby Mountains are composed of three distinct divisions: the East Humboldt Range, Ruby and South Ruby (Figure 2). The East Humboldt Range, which comprises the northern portion, is located north of Secret Pass and south of Wells encompassing an area of 221 square miles. This division embraces extensive summer range for both mule deer (Odocoileus hemionus) and lions. Winter range is limited due to deep snow which forces the deer to migrate considerable distances south and east (Papez 1976).

The Ruby division, located between Secret Pass and Harrison Pass, is the largest unit and contains 362 square miles of mule deer and mountain lion summer and winter range.

The South Ruby division is primarily winter range for mule deer and lions, although some fair to good summer range is present on the west slopes between Harrison Pass and Overland Pass. This area embraces 270 square miles, but generally lacks good water distribution and high quality deer habitat.

South Ruby Mountain Range Lion Habitat

The entire Ruby study area encompasses approximately 853 square miles. The northern third of the Ruby Range and the majority of East Humboldt Range are composed of intermixed private and public lands.

MONITOR RANGE--The Monitor Range extends 97 miles north to south between the general vicinity of Eureka and Tonopah, Nevada. Most of the field work was conducted on the northern 25 miles of the range, primarily from Dobbin Summit north, which included an area of 335 square miles (Figure 3), nearly all of which is on public lands.

General Characteristics of the Environment

Detailed descriptions of the topography, soil, climate and vegetation, which are applicable to the study areas, are presented in the Nevada Department of Wildlife publication titled "The Ruby-Butte Deer Herd" (Papez 1976). Generally, these descriptions also apply to mountain lion habitat throughout the state, with some local modifications, which are well covered by Billings (1951).

In brief, the physiographic characteristics are typical of the Great Basin. The mountains and valleys trend in a north-south direction with elevations ranging from 5,500 feet in the valleys to heights of 9,000-11,000 feet for the mountain peaks. The exceptional Wheeler Peak, in the Snake Range, crests at over 13,000 feet.

Monitor Range Lion Habitat

| 6. Cherry Creek/Egna | |

The climate is typically one of hot, dry summers and cold, wet winters. Maximum precipitation occurs in late winter and early spring and varies considerably by site, being 13-15 inches annually at elevations above 7,500 feet in the study area. Temperatures vary dramatically over a 24-hour period and it is not unusual to record a 50°F spread between the morning low and the afternoon high. Similarly, there is also a great variation between the winter lows and summer highs, such as a -43°F minimum and 107°F maximum recorded in Elko, Nevada. The wide ranging temperatures are a feature of the Great Basin area which makes it prudent for one to carry a down sleeping bag the year around.

The vegetation is typified by a Sagebrush Zone which dominates the valley floors and the lower foothills. Big sage (Artemisia tridentata) is the major species. Big sage and black sage (Artemisia nova) are also well represented in the other vegetational zones which occur in the study area. At the lower elevations of the deer summer range, which would also demark the mountain lion ranges, big sage is associated with bitterbrush (Purshia tridentata) and rabbitbrush (Chrysothamnus vicidiflorus).

On the foothills above the sagebrush zone, but below 7,500 feet, a belt of Pinyon-Juniper (Pinus monophylla - Juniperus osteosperma) becomes the dominant type. This pygmy forest is a very important transitional zone for deer as they move through it from their summer and winter ranges. The major understory plants are sagebrush, bitterbrush, rabbitbrush and serviceberry (Amelanchier alnifolia). Pinyon-Juniper is not significantly present in the Ruby Mountains north of Harrison pass; however, in the Monitor study area it is the dominant vegetation at the lower elevations.

Elevations above 7,500 feet to 9,500 feet are characterized by mountain brush. This summer range is an extremely important zone for deer, and consequently mountain lions, and is dominated by quaking aspen (Populus tremuloides), mountain mahogany (Cercocarpus ledifolius), snowbrush (Ceanothus velutinus), chokecherry (Prunus virginianus), willow (Salix spp.) and wild rose (Rosa spp.).

Along the crests of the mountains at elevations above 9,500 feet, the Alpine-Subalpine forest is found. Limber pine (Pinus flexilis), whitebark pine (Pinus albicaulis) and occasionally white fir (Abies concolor) and bristlecone pine (Pinus aristata) are the dominant trees. Prominent understory species are snowbrush, dwarf juniper (Juniperus communis) and bearberry (Arctostaphylos uva-ursi).

METHODS

Harvest data, which included U.S. Fish and Wildlife Service depredation removal and the Nevada Department of Wildlife sport harvest records, were reviewed to identify mountain ranges throughout the state that contained lion populations. Sight records, of lions or their tracks, obtained by professional government lion hunters, sport hunters and guides, and Department personnel were used to augment harvest data in compiling distribution maps. All records were plotted on 1/250,000 topographic maps and the area of occupied lion habitat was delineated and square miles computed.

The primary methods used for obtaining data was through lion capture, marking and recapture, and from radio-telemetry monitoring. The majority of the capture efforts were conducted during winter months when the ground was covered with snow and tracks could be located by driving roads, snowmobiling or on foot. Once fresh tracks were found, trained hounds owned by government hunters would be started and followed until a successful capture was made or the hounds had to be pulled off the trail due to severe weather, darkness, exhaustion or other reasons. Once a lion was cornered, its weight was estimated and the proper drug dosages prepared for tranquilizing. During the first six years of the study the drugs Sernylan (Phencyclidine hydrochloride) and Sparine (Promazine hydrochloride) were used in combination, with a ratio of 1-3 parts Sparine to 1 part Sernylan, depending on the dart syringe capacity (1.5-3.0 cc). These drugs were used at a rate of 0.1 cc per each 20 pounds of body weight. During the last 4 years of the study the drug Ketaset/Vetalar (Ketamine hydrochloride) was used with considerable success, although the volume required (1 cc per 20 pounds) did present some difficulties because occasionally not all of the drug was absorbed by the muscle. All drugs were manufactured by Park, Davis & Company, Detroit, Michigan. All Cap-Chur syringes, powder charges and guns were supplied through Palmer Chemical and Equipment Company, Douglasville, Georgia.

After immobilization each animal was sexed, weighed and aged. Any injuries, other abnormalities and ectoparasites were recorded. Females were checked for indications of pregnancy, estrus or nursing. Tooth replacement, amount of stain and wear, and a measurement of the upper canines from the gum line to the tips of the labial side of the tooth were recorded for selected lions. During subsequent recapture or harvest any changes were noted. Numbered metal ear tags were placed on some lions early in the study but due to losses were discontinued in favor of numbered rope collars. Once the telemetry program gained momentum radio collars were used. Following data collection and marking the lion was placed in a protected location and allowed to recover.

During the period of 1973-75 lions were instrumented with low frequency radio collars (31 MHz) manufactured by Thomas Owens, Sacramento, California. These collars were either solar powered or a combination solar/nickel cadmium battery units with a life expectancy of less than 6 months. A variety of receiving equipment was used to locate and monitor the radioed lions, but none of it was entirely satisfactory.

During late 1977 more reliable radio collars were obtained from Telonics, Inc., of Mesa, Arizona. These units were of a higher frequency (159 MHz) and were entirely operated by lithium batteries with a theoretical life of up to 44 months. The receiving unit (Telonics Model TR-2) had a direct frequency reading and self-contained rechargeable power pack. Searches and monitoring were conducted from small aircraft and from the ground. Aerial reception varied from 2-30 miles and ground reception from 0.5-20 miles. Some radio collars incorporated a motion sensing device (mercury switch) where non-movement after 3 hours caused an increase in pulse rate (mortality mode) and this feature proved to be very helpful.

FINDINGS

The Mountain Lion

The mountain lion, locally called the cougar, puma, panther or just plain lion, is endemic to Nevada. It is the largest of the unspotted cats in the United States and the sexes are colored alike. The color of adults is tawny or greyish above and whitish below with dark brown on the tip of the long tail, backs of ears and sides of nose. The young are spotted with blackish-brown on a pale fawn ground color. Males are larger than females.

Ninety-seven lions were captured and marked between March 1972 and February 1982 (Table 1). Three of these were captured in western Nevada and 94 from the primary study areas in central and eastern Nevada. The sex and age composition was 57 males and 40 females of which 46 were classified as adults, 16 as subadults and 35 as kittens (see age section for classification criteria).

Fifty-two of the 97 lions were captured and recaptured 116 times and located 695 times through radio telemetry monitoring (Table 2). Many hours and miles were logged in tracking lions on foot which further added to the knowledge of a particular animal. Daily, monthly and seasonal movements were determined for several lions. This monitoring effort made it possible to gain insight on many of the life history subjects presented in this section. Additional information was obtained through the examination of lions killed (for depredations or by sport harvest) during the course of the study.

Distribution

Since mountain lions are adaptable to a great variety of environmental conditions, they are able to occupy most of the mountain ranges in Nevada and are found from the hot southern deserts to the coldest extremes of the northeastern mountains. A generalized distribution map which depicts the probable extent of the mountain lion's range, when considering habitat types and prey base as well as documented lion occurrence, is presented in Figure 4. Based on this map it is estimated that there are 27,811 square miles of mountain lion habitat in Nevada.

Reproduction

Breeding Age -- The average estimated age of first conception for nine female lions which were examined was 29 months, with a range of 22-40 months. Using a 90-day gestation period (Asdell 1964) the average age for giving first birth was 32 months. Eaton and Velandar (1977) found that 4 captive females in Washington state had first birth between 26.5-30 months of age. They also reported that the earliest record of a lion giving birth was 21 months.

No data for sexual maturity of male lions was obtained during this study.

FIGURE 4 Generalized Mountain
Lion Distribution in
Nevada. (27,811 mi²)

Time of Birth -- The month of birth was calculated for 135 litters by projecting forward for prenatal litters and backdating for postnatal litters... No kittens older than 12 months (estimated age) were included in the calculations (see section on aging for criteria). The majority of reproductive tracts examined were from females in the latter stages of pregnancy. Prenatal young were aged based on crown-rump measurements or by the overall size of the fetuses in the case of U.S. Fish and Wildlife Service records. The following measurements are believed to be a reasonably accurate means of determining prenatal monthly age classes:

- (1) First month ----- 25 mm or less
- (2) Second month ----- 26-125 mm
- (3) Third month ----- 126 mm or larger

Kittens were born in every month of the year with a peak occurring during the months of June-July (Figure 5). During April-September a total of 94 litters were recorded (70%) as compared to 41 litters (30%) during the remainder of the year. Robinette et al. (1961) computed birth months for 145 litters in Nevada and Utah and found the peak months to be June-September. In central Idaho Seidensticker et al. (1973) reported most births occurred during late spring and early summer.

Figure 5. Birth Months for 135 Mountain Lion Litters in Nevada, 1956-82.

Frequency of Litters -- Data from 12 adult female lions indicated that the reproductive cycle (time between litters) ranged from 11.5-24 months and averaged 17.4 months.

Litter Size and Survival -- Examination of 36 prenatal litters revealed an average litter size of 3.08 kittens. The number of kittens per litter varied from 1 to 5 as shown in Table 3.

As the kittens grew there was a gradual loss and the number of kittens observed with their mothers declined to an average of 2.23 by the 12th month. Table 4 shows this loss by estimated age group. In analyzing Tables 3 and 4 it would appear that the prenatal litter size of 3.08 kittens is probably higher than the actual number of kittens born. Furthermore, the litter size for the 4-month age group (2.59) would reflect losses from birth to that time. Therefore, it is felt that the actual birth rate lies somewhere between the two and 2.8 kittens was used as the average litter size when calculations requiring this were needed.

5-11 months	6	19	15	2	42	(97)	2.31
12 months	6	25	15	1	47	(105)	2.23
TOTAL	15	58	51	6	130	(308)	2.37

Currier (1976) reported the average litter sizes for Colorado as 1.6 (13)*, California 2.0 (8)*, Arizona 2.2 (11)*, and Idaho 2.4 (33)*, while captive lions in Washington averaged 2.6 (92)*. The sample size in all of these states, except Washington, was very small.

The rate of kitten survival in Nevada is good and when coupled with the lions' high reproductive potential it can be speculated that mountain lions are capable of rapidly replacing individuals that are removed from the population.

*Number of kittens in sample shown in parenthesis

Population Turnover -- Data relating to population turnover was restricted primarily to the Ruby Division, where records from track counts, captures and recaptures, and radio-telemetry locations indicated that the lion population consisted of approximately 35 animals. During the period of 1954-60 there was a sustained mortality on this population of at least 11 lions per year (30% of total). In 1974 and 1975 thirty lions were known to have been removed from the population, with sport hunting accounting for the highest percentage. Yet, three years later (1978), following the initiation of very restrictive sport hunting regulations, this population appeared to have recovered to its former level. This conforms with the findings of Robinette, et al. (1977) who felt that the annual recruitment and mortality of cougars in their Utah study area was 32%.

It appears that under moderate to heavy exploitation (30%-50% removal) Nevada lion populations have the recruitment capability of rapidly replacing annual losses.

Sex Ratios -- U.S. Fish and Wildlife Service and Nevada Department of Wildlife records for the period between 1954 and 1982 show that 83 litters containing 198 kittens had a sex composition of 89 females and 109 males (100 F; 125.5 M). The data clearly shows an unequal sex ratio, in favor of males; however, a large number of litters recorded by the U.S. Fish and Wildlife Service were not sexed and the data base to date may not be representative of true conditions.

Aging -- The terminology used for classifying mountain lion age groups has been confusing to say the least. The term kitten is commonly applied to young lions and in some instances this appellation is used until the youngster finally leaves its mother (approximately 2 years old). Under this connotation the kitten can be newborn, with obvious kitten-like characteristics, or an immature lion which, on superficial examination, cannot be differentiated from an adult -- a broad category indeed. Shaw (1980) not only uses the term kitten but also classified lions in the age group of 0-2 years as subadults. This probably can be attributed to "lion talk" between the professional hunter and the researcher, where they recognize a difference but have not defined it. Seidensticker (1973) related that "as a lion grows older, it passes through a series of relatively discrete behavioral stages: kitten, transient adult, resident adult." He also referred to small kittens and big kittens (over a year old). In this case behavioral stages and age groups could become confusing. Hornocker (1970) refers to kittens, juveniles and adults but offered no criteria for distinguishing them, other than calling a 1 year old a

A Mountain Lion Kitten at Less than 4 Months Showing Distinct Spotting.

kitten. Currier (1976) did set up a rudimentary classification for three age groups: kitten, adolescent and adult, but it is very generalized and there is some major overlap in criteria. The term yearling has also popped up in the literature and in lion discussions and could be interpreted as being interchangeable with kitten or subadult, but also has the connotation of distinguishing a large kitten from a small one. The need for some approach toward standardization of terminology and relating it to criteria has been evident for some time (Mountain Lion Workshop 1976).

When this study was initiated some broad criteria for the general classification of age groups was adopted. As the study progressed additional criteria, primarily relating to tooth eruption and growth, were incorporated into the key. Even now the distinction between the three proposed age groups (kittens, subadults and adults) often requires a subjective evaluation. However, the criteria presented in Table 5, if used, certainly will help eliminate some of the general age classification confusion.

A further refinement, for aging juveniles by months and adults by year, was explored through the use of tooth eruption sequences, growth, stain and wear. Sufficient data was not collected to be statistically sound, and initial ages had to be estimated; however, this information could be a starting point for additional research toward determining ages more accurately.

Teeth from 94 kittens and subadults were examined to develop the eruption

TABLE 5. CRITERIA FOR A GENERAL CLASSIFICATION OF MOUNTAIN LION AGE GROUPS.

KITTENS (0- 16 months)

- * 1. Body weight.
- 2. Pelage spotting; fading by 3rd or 4th month.
- 3. Still with mother.
- 4. Deciduous teeth present or permanent teeth erupting.
(See Table 6 for a guide to estimating kitten ages).
- 5. If all teeth are permanent then canines are not fully extended.
Canine length is less than 28 mm in males and 23 mm in females.

SUBADULT (17 - 23 months) - Has passed through juvenile period but not yet attained typical adult characteristics.

- * 1. Body weight.
- 2. Pelage spotting still present on insides of front legs.
- 3. Not sexually mature. Females not nursing (small teats and no areola).
- 4. May or may not be with mother.
- 5. Full extension of canines. Canines measure 28-31 mm in males and 23-25 mm in females.
- 6. Teeth ivory white in color, not stained.

ADULTS (24 months or over)

- * 1. Body weight.
- 2. Independent of mother.
- 3. No spotting on pelage or very faint.
- 4. Sexually mature. Evidence of nursing in females, large teats and presence of areola (may not be evident in young females just entering this age group).
- 5. Tooth wear and/or stain. (See Table 8 for a guide to estimating adult ages.)

* The following standards are based on weights from Table 1.

Kittens

Males - up to 123 lbs.

Females - up to 81 lbs.

Weight differences between kittens and subadults are obvious up through approximately 9 months. From this age on there can be an overlap and other criteria must be used in conjunction with weight.

Subadults

Males - 115-140 lbs.

Females - 79-105 lbs.

Adults

Males - 112-162 lbs.

Females 84-115 lbs.

TABLE 6. A GUIDE FOR ESTIMATING AGES OF MOUNTAIN LION KITTENS
BY TOOTH ERUPTION SEQUENCES.

Age (Months)	Sequence of Permanent Tooth Eruption
2	Complete set of deciduous teeth; permanent P^2 and M^1 erupted
3	Permanent incisors erupted
4	Upper canines and P^4 erupt
5	M_1 and lower canines erupt
6	P^3 erupts
7	P_4 erupts
8	P_3 erupts; upper canines 50-60% extended from gum lines (males: 16-18 mm, females: 12-14 mm)
9 & 10	P^4 , M_1 , and P^3 become fully extended
11 & 12	P_4 and P_3 fully extended; upper canines 70-80% extended (males: 20-22 mm, females: 15-17 mm)
13 & 14	Upper canines 80-90% extended (males: 24-27 mm, females: 19-21 mm)
15 & 16	Upper canines fully extended by 16th month (males: 28-31 mm, females: 23-25 mm)

TABLE 7. CRITERIA FOR ESTIMATING AGES OF ADULT MOUNTAIN LIONS.

2 YEARS OLD

1. Canines white, no staining.
2. No wear on incisors 1 and 2. Third incisor may show slight wear.
3. Tips of canines show little or no wear.

3 and 4 YEARS OLD

1. Canines lightly stained.
2. Slight wear on highest point of crown of third incisor. Area of wear 1-4 mm across.
3. Incisors 1 and 2 with little or no wear.
4. Tips of canines with little or no wear (2 mm or less).

5 and 6 YEARS OLD

1. Canines moderately stained.
2. Third incisor worn to within 1-4 mm of crest of incisors 1 and 2.
3. Incisors 1 and 2 have slight to moderate wear along crown.
4. Tips of canines with obvious wear (3-5 mm worn off).

7-9 YEARS OLD

1. Canines darkly stained.
2. Third incisor worn level with incisors 1 and 2 and to within 1-4 mm of gum line.
3. Tips of canines flattened to nearly rounded.
4. Dentine exposed on incisors.

10 + YEARS OLD

1. All incisors worn nearly to gum line, or missing.
2. Canines worn rounded to blunt, darkly stained.

FIGURE 6 Lateral view of a mountain lion skull with letter/number designations for permanent dentition.
Drawing by M. Alderson.

FIGURE 7 Frontal view of upper teeth of female and male mountain lions displaying relative wear by adult age classes.
Drawing by M. Alderson.

Drawing by M. Alderson

sequences and to formulate the aging guide shown in Table 6. Of this number 21 were kittens or subadults which had been captured, marked, their age estimated, and then released. When these animals moved into the adult age group they provided information concerning tooth stain and wear which was used to help develop Table 7. Figures 6, 7 and 8 illustrate permanent dentition and adult lion tooth wear patterns.

Although not shown in Table 7 there is some evidence available to show that there is differential wear on the canines and incisors of males versus females.

Weights -- Only limited data was collected on the weights of newborn kittens. Nine fetuses, judged to be in the last 2 weeks before birth, had a weight range of 0.77-1.17 pounds. Two kittens estimated to be 1-3 days of age weighed 1.06 and 1.17 pounds.

The weights of all captured lions are provided in Table 1. Based on 21 lions the adult males ranged from 112 to 162 pounds and had an average weight of 137 pounds. Thirteen adult females ranged from 84 to 115 pounds and averaged 98 pounds. The average weights recorded for lions in California was 105.8 pounds for males and 76.5 pounds for females; in Arizona, 114.5 pounds for males and 72.6 pounds for females; and in Utah, 136.9 pounds for males and 92.5 pounds for females (Sitton, 1977).

Movements

Dispersal of Juveniles -- Data was obtained from 8 family groups as to the approximate age of the kittens when they separated from their mothers. The range in ages was 10.5 months to 19 months with an average of 14 months. It was observed on several occasions that following separation from their mothers the young frequently remained in their home range for a time before finally dispersing.

To become established as part of the breeding population a newly independent mountain lion normally progresses through three phases:

- (1) Independent kitten or subadult -- upon leaving its mother.
- (2) Transient - when searching for a new home range.
- (3) Resident - upon establishment of a new home range.

This behavioral pattern is similar to that observed by Seidensticker, et al. 1973, with the important exception that Seidensticker called all transient and resident lions adults. In contrast, the data from this study shows that when using the age classification groups in Table 5 transients can be kittens, subadults or adults and residency can be established by subadults. Behavioral patterns do not necessarily establish the age of the lion.

The transient phase can be very limited, particularly with females, as was observed with lion number 13 who stayed in the mountain range of her birth, was bred at the approximate age of 24 months, and established a home range immediately adjacent to her mother's (number 14).

Documented movements recording the dispersal of 16 young mountain lions in the Ruby Mountains and vicinity are shown in Figure 9. Eleven of these lions stayed within the mountain range where trapped (and believed to have been born) and 8 left to become established in another mountain range. Travel routes were unknown for the lions that left their home range but it is presumed they sometimes had to cross wide, barren valleys to reach their new residence. Of the 8 males tracked only 2 remained in the mountain range where first captured and presumably born. Females generally did not move as far as males (averaging 18 miles as compared to 31 miles for males) and they tended to remain in the mountain range where they appeared to have been born. Extreme movements of 36 miles for a female and 57 miles for a male lion were noted. The initial dispersal of independent kittens or subadults from their home ranges appears to be an important characteristic which contributes towards maintaining viable populations throughout their habitat. For example, in areas where mountain lions are heavily exploited (see Mortalities), such as in the Ruby Mountains, the influx of transient lions is essential in order to maintain a population.

Home Range -- Sufficient data was obtained from radio-tracking, recaptures and track sightings to at least partially construct the home range size of 13 lions. This data covered a time period which ranged from 15-77 months per lion and involved anywhere from 17-116 locations per lion (Table 8). Male lions had home ranges three times as large as females averaging 224 square miles as compared to 69.5 square miles (Figures 10-22). It is believed that smaller home ranges in the Ruby Mountains were due to higher deer densities compared with the other mountain ranges. Females occupying the South Ruby portion had considerably larger estimated home ranges than females living in higher deer density habitat in the North Rubies.

Home range overlap was documented for both adult females and adult males; however, sufficient long-term data was not collected to determine if resident lions were being recorded in all cases. In fact, the high lion turnover rate in the study area made it very difficult to distinguish between transients and residents, and in determining resident home ranges some judgements had to be made. Male home ranges either partially or completely overlapped those of neighboring adult females. Less overlap was found between members of the same sex, although on occasion there was considerable overlap during certain seasons. This occurred most frequently during the middle of winter when both deer and lions were concentrated and again during the spring and early summer (primary breeding season).

Both adult males and females tended to use the same areas month after month and year after year within their home ranges. This behavior was similar to that described by Hornocker (1969) and Seidensticker et al. (1973) in Idaho. However, there were some differences between characteristics recorded in Idaho lion populations and those observed in Nevada: (1) males were observed to fight and were not generally tolerant of each other in regard to intrusions into their home ranges, and (2) there was no obvious differences, in regard to home range size, between unexploited and exploited lion populations.

Seasonal Movements -- With the advent of winter snows in late fall the deer move to lower elevations or migrate to traditional winter ranges. The mountain lion normally follows, but may go to the wintering grounds of another

herd. In doing so there may be a movement to a different mountain range and long distances can be traversed (Figures 12 and 13).

Lions usually avoided north-facing slopes in the winter when snow was deep and crossed from one drainage to another by descending to the mouth of the canyon. South-facing slopes received the most use because of less snow and the presence of greater numbers of deer. Snow, however, did not always deter the mountain lion, and they have been noted to cross over mountain passes covered with 3 to 5 feet of snow with little difficulty.

During the summer months the lions' movements were not restricted by environmental factors. North-facing slopes, which were cooler and had more vegetation than south-facing slopes, were preferred. The vegetative cover in the Ruby Mountains is sparse above 9,000 feet (subalpine zone) and lions tended to use these areas much less than the lower elevations where aspen, mountain mahogany and taller shrubs were prevalent. The highest elevation at which a lion was located was 10,400 feet and the lowest was 6,100 feet. The elevational zone of highest use by lions in eastern and central Nevada is between 6,500 and 8,500 feet where deer and other prey species are most abundant.

Movements of Deer in Relation to Lions -- On one occasion deer were observed fleeing in response to a lion's presence, while in other instances they tended to either ignore the lion or they appeared only slightly nervous, often looking in the direction of the lion. Most of these observations were made when deer were in open areas which lacked suitable stalking cover for lions. In one instance several deer were seen to wander into a dense grove of mahogany trees where a lion was present. Within a few minutes the deer walked out of the trees, seemed to be uneasy and frequently looked back in the direction of the lion but did not run. On another occasion several deer were noted to be fearful of a nearby lion and they ran approximately 300-400 yards until they reached an open hillside where they stopped and began to feed.

Food Habits -- The most comprehensive study on food habits of the mountain lions in Nevada was made by Robinette, et al. (1959). Although the emphasis in this study was not directed toward food habits, data was collected when possible. These findings showed that mountain lions ate a variety of prey species ranging in size from wood rats (Neotoma spp.) to elk (Cervus canadensis). The staple food was the mule deer. In some areas feral horses rated second in importance if deer densities were low. In the Ruby Mountains, beaver (Castor canadensis) were a favorite food source and were readily available. Another prey species not listed, but of local importance in southern Nevada, was the bighorn sheep (Ovis canadensis).

Two hundred lion scats were examined during the ten years of field effort and the following food items (listed in approximate order of importance) were found: mule deer, porcupine (Erithizon dorsatum), cottontail rabbit (Sylvilagus spp.), jackrabbit (Lepus californicus), feral horse, beaver, domestic sheep, wood rat, blue grouse (Dendragapus obscurus), coyote (Canis latrans), bobcat (Lynx rufus), unknown rodents, and elk.

In addition to scats, the contents of 14 lion stomachs were examined. This information is presented in Table 9.

Mortalities

Livestock Depredations -- Since 1916 the U.S. Fish and Wildlife Service has attempted to control mountain lion populations in those states where livestock depredations were considered a problem. The Service still maintains this posture in Nevada, although they recognize that mountain lions are resident wildlife, classified as game animals, and that the State has authority for overall management of the species. However, the Service, under the terms of a cooperative agreement, has the authority for control of mountain lion depredations. This agreement states that mountain lions may be taken:

1. When they are causing or are about to cause damage to personal property. This will be coordinated with the respective State wildlife agency on a case-by-case basis; or
2. During nongrazing seasons in specific geographical areas where they have been causing damage and could not be captured during the depredation season and continuing damage is expected during the ensuing grazing season. This post-grazing season corrective control on mountain lions may be done after consultation with and concurrence of the respective State wildlife agency on a case-by-case basis; or
3. Under preventive control measures in a historically, serious, documented depredation area. Preventive control may be authorized by the Area Manager when previous steps have failed and after consultation with and concurrence of the State wildlife agency.

As a compliment to this cooperative agreement, and also as a guide for the Department, the Nevada Department of Wildlife Board of Commissioners has adopted Commission Policy No. 14 which relates to Animal Damage Control. This policy is attached in Appendix A.

SHEEP - In Nevada, mountain lion depredations upon domestic sheep has always been a controversial issue. Since domestic sheep summer use areas often coincide with occupied mountain lion habitat most depredations occur during this time. After the lambs are sold in the fall the adult and replacement ewes are usually trucked or trailed to winter ranges. Some bands of sheep in eastern Nevada are trailed as far as 400 miles (round trip) to and from winter and summer ranges. The winter sheep bands are not normally preyed upon by mountain lions to any significant degree. However, if sheep are allowed to move into tree cover or near rock outcrops, depredations are likely to occur.

The pregnant ewes are trailed or transported from the winter ranges to lambing grounds which are used during the spring months until higher elevations are free of snow and the forage has made its initial growth. These staging areas are located on public (B.L.M.) or occasionally private lands. Lion depredations on lambing grounds, although not normally as severe as on summer ranges, do occur on occasion.

Fifteen lambs killed by a mountain lion overnight.
The carcasses were gathered together to take the photo.

Although the number of sheep grazed in Nevada 20 or 30 years ago is not accurately known, it has been estimated that there were 3 to 4 times as many then as today. As recently as 1978 there was an estimated 80,000-90,000 adult sheep utilizing summer ranges in eastern Nevada. Total numbers, including lambs, were approximately 160,000-180,000 head. Since 1980 the summer ranges in eastern and central Nevada have been stocked with approximately 130,000-150,000 head of sheep (adults and lambs) per year. Table 10 lists the mountain ranges (or geographic areas) in these summer ranges and also depicts the number of domestic sheep and estimated lion populations for each area. Assuming these estimates are reasonable there is a ratio of one lion for each 1,346 sheep on these summer ranges.

The confirmed sheep losses to lions in eastern and central Nevada for the years 1978-81 are as follows:

<u>YEAR</u>	<u>MINIMUM NUMBER SHEEP LOST</u>	<u>APPROXIMATE DOLLAR VALUE</u>
1978	230	\$16,100
1979	231	14,300
1980	380	28,700
1981	234	16,600

In some cases unconfirmed kills (those reported by herders but not verified) occurred in addition to the confirmed losses. However, these losses are believed to be less than 20% of the confirmed losses. Even if the number of sheep killed by lions was double the confirmed loss the percentage would be small compared to the total number of sheep grazed. For example, in 1982 (Table 10) an estimated 140,000 sheep were grazed in eastern and part of central Nevada. If lions killed 500 sheep the loss would amount to only 0.35% of the total number grazed. Even though total losses are not significant to the livestock industry as a whole, impacts to an individual operator are, at times, quite significant. For example, in 1978 one operator in the Ruby Mountains lost sheep valued at \$6,100 during a 3-month period and another operator, in the Schell Creek Range, sustained losses of \$8,000 during the same year.

CATTLE AND HORSES - For some unexplained reason cattle are not preyed upon by lions in Nevada to a significant degree. Both lions and cattle use the same areas during the summer months. Cattle are as available or even more so than are domestic sheep. The basic difference between cattle and sheep operations is the sheep are herded in large dense groups while cattle are allowed to roam individually within an allotted area. Cattle can become somewhat concentrated at times when they must congregate around a water supply or along a stream where succulent vegetation is available. The large size of cattle may preclude some attacks by lions but calves usually weigh less than 400 pounds and can easily be killed by an adult lion. Counts which are made when cattle are turned out in the spring and again when rounded up in the fall show losses from all causes are small. This indicates that lion depredations on cattle in Nevada is probably not significant in most areas.

Occasionally there are reports of lions attacking, injuring or killing domestic horses. Since most horses are kept within the confines of a corral or fenced pasture and away from lion habitat, depredations are infrequent.

TABLE 10. SUMMER USE AREAS FOR DOMESTIC SHEEP, AND MOUNTAIN LION POPULATION ESTIMATES IN EASTERN AND CENTRAL NEVADA, 1982.

<u>Mountain Range</u>	<u>Number of Domestic Sheep¹</u>	<u>Estimated Number of Adult Lions Present²</u>

¹In most cases the number of sheep includes lambs, calculated at 1 lamb per each adult ewe. Some bands, e.g., Stag Mountain, are dry ewes.

²See population section for information on arriving at lion population estimates.

Depredation Harvest Reports

The U.S. Fish and Wildlife Service first began keeping records of the number of lions taken by government trappers and hunters in 1917 (Table 11). The sex of lions killed was recorded for the years 1917-1956 and again from 1969-1981. More males (527) were taken than females (438) with a ratio of 100 F : 120 M. During 1917-1968 many lions were removed in anticipation of future problems and the lion hunters were particularly active from 1956 through 1961. This preventative treatment resulted in lions being killed that were not responsible for depredations. In recent years (1969-1981) most of the lions which were harvested were known to be killing sheep and this was confirmed by examination of stomach contents.

Lion Mortalities in Eastern Nevada

The highest deer populations, the greatest number of lions, and the heaviest use of lion habitat by domestic sheep all center in eastern Nevada. Furthermore, eastern Nevada has historically been one of the better lion sport hunting areas and, consequently, became a favorite area of guides and their clientele. It is no wonder then that most conflicts revolving around the mountain lion occur in this portion of the state.

In analyzing data from the Ruby Mountains, the Cherry Creek-Egan area, and the Schell Creek Range, all of which have a long history of domestic sheep depredations, it was found that there were 146 documented lion mortalities during the period of 1972-81 (Table 12). Of this number 61 (41.8%) were directly associated with domestic sheep depredations.

From 1969-1982, when both sport hunting and depredation harvest have been recorded, there has been 645 lions killed for sport and 272 for depredations statewide (Table 13). The depredating lion harvest of less than 30% clearly shows that on a statewide basis the sheep depredation problem is not nearly as serious as in the study area and again demonstrates the conflict that arises from placing sheep in lion country. Over a similar period of time (1972-82) depredating lions comprised 54% of the mortality recorded from the 97 lions which were marked for this study (Table 14). So once again it becomes apparent that lions and sheep do not mix well. However, an important point to recognize is that the reverse side of the coin shows that there are many lions in the State that are not involved in depredations and that the present agreement between the Department of Wildlife and the U.S. Fish and Wildlife Service concerning livestock depredations, and restricting lion kills to the offending animal, is a great advancement in proper lion management.

Sport Harvest

The lion's classification was changed by regulation from unprotected (predator) to game animal in 1965. The initial impact of this classification was the requirement of a valid hunting license to hunt mountain lion and some restriction in the method of taking. This provision precluded the taking of lions at any time other than from sunrise to sunset and also defined legal weapons as shotgun, rifle, or bow and arrow. The season was defined as either sex, year-round and no limit was set nor was a tag required.

In 1968, a tag requirement was imposed, and although no limits were established, it became possible to record sport hunter harvest. A major change occurred in 1970 when a limit of one lion per person was set and a six month season established. During this period, the requirement that all harvested lions be validated by a representative of the Department of Wildlife within five days after the kill was also established. This regulation presented the Department the first real opportunity to collect biological data.

In 1976, twenty-six mountain lion management areas were described statewide and a harvest quota established for each to control the sport harvest. This Controlled Quota Hunt was the most restrictive season ever established for mountain lion in Nevada.

In 1979, the Controlled Quota Hunt was modified for six of the management areas, whereby a kill objective was established which allowed the hunting of lions in the area assigned until the predetermined harvest objective was reached. In 1981 this Harvest Objective hunting season concept was applied to all 26 management areas.

Sportsman participation in lion hunting has fluctuated considerably through the decade of the 1970's as a result of the many and varied season frameworks and regulations. Despite the increase in human population the sport harvest of mountain lion has not increased during the past 10 years. The sales of resident lion tags have never exceeded 500 and averaged 275 over the 1968-81 period. The resource is presently meeting the demand for sport harvest. Table 13 presents the sport harvest data from the years 1969-70 and

Sport Harvest of Mountain Lion Is Almost Exclusively Accomplished with the Aid of Trained Hounds.

*Sport Hunter Harvest Only

1981-82. A summary of the sport hunting seasons and regulations in Nevada since the lion was classified as a game animal in 1965 is presented in Appendix B.

Population Estimates

The mountain lion is a low density predator of secretive nature whose traits make it very difficult to monitor. Several methods were used to estimate mountain lion populations and after experimenting with a number of census techniques it was determined that there were three methods which, depending on local circumstances, were best suited for use in Nevada. These were: 1) Analysis of harvest data, 2) Track counts, and 3) Home range size.

Harvest Data -- The annual harvest can reflect the population level and the analysis of historical and current harvest data provides a base which can be used in making judgements concerning population trends. Hunter success measures the ease with which the sport hunter obtains his quarry and, barring unusual circumstances which must be taken into account, will reflect availability.

In examining both sport harvest and depredation harvest records from the time that they were both recorded statewide (1969-70 through 1981-82) it is obvious that the harvest rate has never been high (Table 13). The greatest influence on the sport harvest appears to have been the initiation of the hunter quota system in 1976-77. This resulted in over a 50% decrease in harvest when comparing the 7 years prior to the quota system and the 6 years following it. However, as hunters are becoming adjusted to the system, and refinements have been made to encourage them into the quota areas, the harvest is again climbing to what appears to be normal levels. Depredations harvest, for the most part, has remained relatively constant (Statewide) with a seven year harvest average of 20 lions annually before the hunter quota system and a six year average of 21 lions annually following the quota system. On an overall basis the statewide lion population trend between 1969-82 appears to be stable.

Track Counts -- Two track count methods have been used: ground surveys and aerial surveys. The ground surveys were begun 3-6 days after a fresh snowfall and were made on foot, with snowmobiles, or by driving roads with pick-up trucks. Each track was classified, if possible, as to sex and estimated age using criteria similar to that recently described by Shaw (1979). The ground count required sampling a large area in a short time frame in order to provide a representative sample. Due to man-time commitments annual ground count surveys are not possible to implement on a statewide basis.

Aerial surveys were done with a helicopter and in a manner similar to the ground surveys except that nearly every drainage in a predetermined geographic area was flown. Each drainage was flown twice, once following the bottom and again following the south exposures where lions were most likely to be found during the winter months. Once a track was sighted the helicopter was landed or hovered over the track while one observer disembarked and the track was classified and recorded. All helicopter surveys were completed in 2 days or less so accuracy could be maintained. Snow, air and light conditions had to be optimum in order to observe tracks, land, and record data. This is the preferred method and was utilized in the major mountain lion areas during the later years of the study. Since the termination of the study this method has not been used because of the high cost.

Home Range -- It was found in eastern Nevada that adult female lions had an average home range of 69.5 square miles and males 224 square miles. However, it was also noted that the home range size for individual lions varies considerably from one mountain range to another. It was recognized that the data available on home range sizes was not as comprehensive as desired; however, it was the most accurate data available for use in computing lion densities.

Mountain Lion Population Estimates by Mountain Range -- When the Harvest Quota system was implemented in 1976 (this was a Department of Wildlife recommendation to resolve controversies over lion management between protectionists, depredation harvest proponents, and sport harvest proponents) it was necessary to define mountain lion management areas, estimate the number of lions (all age classes) in each, and set a harvest quota which would not exceed the annual recruitment to the population.

It was found that track count information was simply too limited in nature to provide a statewide approach toward determining lion populations. However, long-term harvest data did provide a general idea as to the lion population status on a statewide basis. In utilizing this information, as well as the available deer density data, Regional personnel were able to form opinions as to the general quality of the lion habitat in their areas of concern. These judgements and data were then coupled with the basic lion home range parameters from the study area and utilized to formulate lion density factors for the inhabited mountain ranges in Nevada (Table 16). Field personnel then computed the square miles of occupied habitat (based on long-term distribution records) and with this information in hand they then calculated the estimated lion populations. Population estimates have been made since 1976 and in carrying these forward to 1982 it has been computed that 792 mountain lions occupy 27,811 square miles in 104 mountain ranges in Nevada (Table 16).

Harvest Quota Calculations -- The Department of Wildlife's mountain lion harvest objective is to harvest the number of lions which can safely be removed by both depredation and sport hunting and still maintain a viable breeding population (sustained yield). The estimated annual recruitment for lion populations in Nevada is believed to be about 30% (see Population Turnover). Therefore, a harvest objective for 1982 would be 0.3×792 (estimated lion population) = 237 lions. However, this objective was tempered on the conservative side by using a factor of 0.25 rather than 0.3 and instead of using the population estimate of 792 lions the number 550 (which represented the estimated lion population in areas opened to hunting) was used. This resulted in a harvest quota of $.25 \times 550 = 138$ lions. Some local adjustment was made to this quota by area biologists and the final quota for 1982 was 135 lions.

This system of arriving at a harvest quota clearly denotes the maximum number of lions which could be harvested. It then reflects a conservative attitude by slightly reducing the recruitment factor for making computations, and it makes allowances for areas of concern by individual biologists who can request further reasonable reductions or increases.

Goals

Goal: Maintain Nevada's mountain lion populations.

1. Problem: Changing and differing public attitudes about the mountain lion's worth and role in the ecosystem make it a difficult species to manage.
 - a. Strategy: Continue to closely monitor lion populations and the affects of sport hunting, and depredation removal. Maintain consumptive use levels consistent with the lion's ability to sustain that use.
2. Problem: Lion depredations on livestock and wildlife represents an ongoing problem.
 - a. Strategy: Continue a cooperative agreement with the U.S. Fish and Wildlife Service and insure that only offending depredating lions are removed.
 - b. Strategy: Where mountain lion depredations are found to be responsible for suppressing the segment of a wildlife population at or below the "threshold" level the mountain lion population involved may be reduced temporarily to allow the suppressed wildlife prey population to increase thereby ultimately resulting in a potential increase in the mountain lion population due to the larger prey base.
3. Problem: Human-lion conflicts can be anticipated in the future with continuing urban growth.
 - a. Strategy: Develop a program to rapidly and safely handle lion complaints in urban areas.

RECOMMENDATIONS

There are several areas where further study could provide answers and direction for mountain lion management in Nevada. Some of these are:

1. More refined population estimates are needed, especially for low to moderate lion densities.
2. Additional investigations should be made in regard to home range overlap.
3. Lion population turnover should be determined more precisely for both exploited and unexploited populations.
4. Additional data is needed on the effects of lion predation on deer. This was an area that was not adequately investigated during this study. Do lions, in fact, exert control over low-moderate density deer populations?
5. Lion aging techniques should be pursued with an effort to obtain adequate information to supplement and validate the keys presented in this publication.
6. It is felt that lion density ratios should be modified slightly in order to provide more latitude for the field biologist when developing his lion harvest quota recommendations. The following changes are recommended:

1/25 should be changed to 1/20-30
1/40 should be changed to 1/31-45
7. It is apparent to the editor that there were many lost opportunities during the conduct of this study. The plan for achieving the study objectives and the monitoring system for seeing that the annual work program was accomplished, even though in place, was not adhered to. Consequently the researcher often strayed from the study plan and at times data was not collected or was recorded incorrectly. Such failings are not uncommon in Fish and Wildlife research where the dilution of manpower, because of pressing everyday needs, often results in insufficient supervision and/or monitoring. However, since Nevada is still faced with becoming even more involved with mountain lion research, past inadequacies should be recognized and every effort made to strengthen the supervision and monitoring of future studies.

APPENDIX A

STATE OF NEVADA BOARD OF WILDLIFE COMMISSIONERS

	Number:	14(1)
	Title:	Animal Damage Control
Commission Policy No. 14	References:	NRS 501.105, 501.110, 503.470, 503.595, 567.010 through 567.090, CGR No. 1(8) and CGR No. 4(2).
Ammendment No. 1		
	First Reading:	March 13, 1981
	Second Reading:	April 17, 1981
	Effective Date:	April 17, 1981

PURPOSE

To inform the public and guide the Department of Wildlife in actions relating to animal damage control.

In accordance with NRS 501.181, the Board of Wildlife Commissioners shall establish policies for the protection, propagation, restoration, transplanting, introduction and management of wildlife in this state. Further, the Commission shall establish policies for areas of interest including animal damage control.

POLICY

1. Major mammalian predators (coyote, mountain lion, bobcat) will be managed to minimize livestock losses from predation and minimize excessive wildlife losses from predation without endangering the existence or natural role of these predators in the ecosystem.
2. Nonpredatory wildlife will be managed to minimize their vulnerability to excessive predation. Animal damage extension efforts will be encouraged to assist private operators in husbandry practices to minimize the vulnerability of domestic livestock predation.
3. Support continued federal leadership in the Animal Damage Control program because of the national need for development and use of more efficient and humane control methods.
4. Recognize the U.S. Fish and Wildlife Service, Division of Animal Damage Control, as the authority for predator control under cooperative agreement with the Department of Wildlife, where the Department of Wildlife is an active participant in documenting the need for control programs, in planning and execution of control programs, and in enhancing public understanding of these programs.

The Department shall prepare an annual work program for predator control needed for the management of wildlife and recommend that a maximum of \$20,000 annually be forwarded from the wildlife account in the state general fund to the state predatory animal and rodent committee for predatory animal control work as provided in Chapter 567 of NRS.

5. Initiate predator control efforts on the basis of the best biological information available.
6. Direct predator control efforts including sport hunting and trapping, whenever possible to prevent damage before it occurs in specific areas known to be recurring problem areas or alleviate damage as soon as possible after it occurs.
7. Direct predator control efforts at the offending animal, in so far as possible and feasible.
8. Employ predator control methods which are selected on the basis of the species involved, utilizing currently approved methods in the proper mix according to the needs. These methods may include aerial hunting, M-44, trapping, snares, denning and predacides.
 - a. Predacides should only be used in certain preventative and corrective damage control operations using a delivery system which is selective, effective and efficient.
 - b. Aerial hunting will be conducted only under Department of Wildlife damage control permit and limited to bobcats and coyotes. Such permits shall be issued only to the U.S. Fish and Wildlife Service or to landowners or tenants of land or property that is being damaged by wildlife.
9. The Department upon issuance of a depredation permit and with the aid and cooperation of the complainant, may take all available professional and economically feasible measures to alleviate or lessen the depredation problem.

PROCEDURE

NRS 503.595 provides that after the owner or tenant of any land or property has made a report to the Department indicating that such land or property is being damaged or destroyed, or is in danger of being damaged or destroyed, by wildlife, the Department may, after thorough investigation and pursuant to such regulations as the Commission may promulgate, cause such action to be taken as it may deem necessary, desirable and practical to prevent or alleviate such damage or threatened damage to such land or property.

The Commission has adopted regulations authorizing the Director or his designee to issue wildlife depredation permits. Specific permit programs include:

1. An annual wildlife depredation permit may be issued to the State Supervisor, U.S. Fish and Wildlife Service, Division of Animal Control, to take depredating mountain lion or bobcat in the immediate vicinity of threatened livestock.
 - a. Any report of livestock depredation received by the Department of Wildlife shall be forwarded immediately to the permittee for action in accordance with subsection (b) of this section.
 - b. Upon receipt of a report from a livestock owner or the Department indicating that a mountain lion or bobcat is causing or about to cause damage to livestock, the permittee shall conduct an on-site investigation. If the results of the investigation support the complaint, the permittee may take the animal. If the permittee cannot determine if the complaint is valid, he shall notify a representative of the Department, who shall conduct a joint investigation to make the final determination.
 - c. During November through April, the permittee shall slavage and give the hide and skull of depredating mountain lion or bobcat to the Department within 72 hours. During May through October, the permittee shall completely destroy the animal, except the skull which shall be delivered to the Department.
2. An annual wildlife permit may be issued to State Supervisor, U.S. Fish and Wildlife Service, to take the minimum number of mountain lions, bobcats, foxes, cottontail rabbits, pigmy rabbits, white-tailed jack rabbits, bears and squirrels as necessary to control damage to persons and property.
3. Upon receipt of a valid mountain lion or bobcat complaint from an individual livestock owner, the Department may issue a limited permit to the owner to take an animal that is in the act of killing his livestock.
 - a. The permittee shall notify a Department representative within 72 hours after taking a mountain lion and arrangements will be made for examining the skull and sealing the hide.

- b. Mountain lion or bobcat hides, after being properly sealed, may be retained by the permittee to defray the cost of handling the depredation complaint.
4. The Department may issue permits authorizing the hunting or killing of coyotes or bobcats from an aircraft.
 5. Fur-bearing animals injuring any property may be taken or killed at any time in any manner, provided a permit is first obtained from the Department. The Department is authorized to enter upon the lands of a landowner and remove beaver or otter for the relief of other landowners and the protection of the public welfare.
 6. The Department may issue permits consistent with Federal law to take bald eagles or golden eagles whenever it determines that they have become seriously injurious to wildlife or agriculture or other interests that the injury can only be abated by taking some of the offending birds.
 7. The State Predatory Animal and Rodent Committee shall enter into agreements with the U.S. Fish and Wildlife Service covering cooperative control of crop-destroying birds in addition to predatory animals and rodents to assure maximum protection against losses of livestock, poultry, game birds, animals and crops on a statewide basis. The State Department of Agriculture in accordance with NRS 555.010 and 555.021 responds to complaints involving vertebrate pests (excluding predators) that are injurious to agriculture or public health.
 8. The Department may issue a wildlife depredation permit to a landowner if needed for the prevention or alleviation of damage to standing or stored agricultural crops.

This policy shall remain in effect until amended, repealed or superseded by the Board of Wildlife Commissioners.

BY ORDER OF THE BOARD OF WILDLIFE COMMISSIONERS IN REGULAR SESSION,
APRIL 17, 1981.

Marvin A. Einerwold, Chairman
Board of Wildlife Commissioners

APPENDIX B

MOUNTAIN LION HUNTING SEASONS 1965-1982

1965-1966

Type of Season: Either sex, statewide.
Season Length: Open year-round.
Limit or Quota: None.
License and Tag Requirement: Hunting license only.
Special Regulations: Unlawful to hunt with revolver or by use of artificial light.

1967

Type of Season: Either sex, statewide.
Season Length: Open year-round.
Limit or Quota: None.
License and Tag Requirement: Hunting license only.
Special Regulations:
 1. Unlawful to use a revolver.
 2. Unlawful to use artificial light.
 3. Unlawful to trap lions.

1968

Type of Season: Either sex, statewide.
Season Length: Open year-round.
Limit or Quota: None.
License and Tag Requirements: Hunting license and tag.
Special Regulations:
 1. Unlawful to use revolver.
 2. Unlawful to use artificial light.
 3. Livestock operator can take lions with proper permit.

1969

Type of Season: Either sex, statewide.
Season Length: Open year-round.
Limit or Quota: None.
License and Tag Requirement: Hunting license and tag.
Special Regulations:
 1. May be hunted anytime day or night.
 2. Lawful to use any weapon except crossbow.
 3. Livestock operator can take depredating lions at any time.

1970

Type of Season: Either sex, statewide.

Season Length: October 10, 1970 - March 31, 1971 (171 days).

Limit or Quota: 1 per person.

License and Tag Requirement: Hunting license and tag.

Special Regulations:

1. Mandatory check-in of lion hide, skull and stomach contents within 5 days of harvest.
2. Hide must be sealed by a Department representative within 5 days of harvest.
3. Lions may be hunted anytime day or night.
4. Lawful to use any weapon except crossbow.
5. Livestock operator can take depredating lions at any time after issuance of a permit.

1971-1975

Type of Season: Either sex, statewide.

Season Length: Open year-round (1974 & 1975, 6 month season).

Limit or Quota: 1 per person.

License and Tag Requirement: Hunting license and tag.

Special Regulations:

1. Mandatory check-in of lion hide and skull within 48 hours of harvest (1973, 72 hours of harvest).
2. Hide must be sealed by a Department representative within 48 hours of harvest.
3. Lions may be hunted anytime day or night.
4. Lawful to use any weapon except crossbow.
5. Livestock operator can take depredating lions at any time after issuance of a permit.

1976-1978

Type of Season: Either sex, statewide.

Season Length: 1976 - October 1, 1976 - March 31, 1977 (6 months).

1977, 1978 - October 1, 1977 - April 30, 1978 (7 months).

Limit or Quota:

1. One lion per person.
2. Resident and nonresident quotas by management area and through application only.

License and Tag Requirement: Hunting license and tag.

Special Regulations:

1. Mandatory check-in of lion hide and skull within 72 hours of harvest.
2. Hide must be sealed within 72 hours of harvest.
3. Lions may be hunted any time day or night.
4. Lawful to use any weapon except crossbow.
5. Livestock operator can take depredating lions any time after issuance of a permit.
6. Accidentally trapped lions are the property of the State of Nevada and shall be reported within 48 hours of capture.

1979-1980

Type of Season: Either sex, statewide.

Season Length: October 1, 1979 - April 30, 1980 (7 months).

Limit or Quota:

1. One lion per person.
2. Resident and nonresident "Trophy General Hunt" with quotas by management area, application only.
3. Resident and nonresident "Controlled Trophy Hunt" with quotas (allowable harvest) by management, application only.

License and Tag Requirements: Hunting license and tag.

Special Regulations:

1. Any person holding a valid tag for lion in management area 7, 8, 9, 10, 19, 20 or 21 (1980) obtain a 15-day controlled hunt permit at no cost before hunting.
2. Permit will be valid in a specified management area for 15 days. Unsuccessful hunters may reapply for the same or another management area if the harvest quota has not been filled. Hunters holding a 15-day permit will be notified by the Department when the harvest quota is filled for that area. The hunter may then reapply for another open area.
3. Mandatory 72 hour check-in and hide sealing required.
4. Accidentally trapped lions are the property of the State of Nevada and shall be reported within 48 hours of capture.

1981

Type of Season: Either sex, statewide.

Season Length: October 1, 1981 - April 30, 1982 (7 months).

Limit or Quota:

1. One lion per person.
2. Unlimited tag quota by application only.
3. Harvest quota by management area.

License and Tag Requirement:

1. Hunting license and tag.
2. 15-day permit.

Special Regulations:

1. Hunting permit reservations may be made by mail, telephone or appearing in person at the designated Department offices.
2. Hunting permits will be valid in a specified management area for a period of 15 days from the date of issue. If a hunter fails to harvest a lion in the specified period and management area, he may reapply as many times as he desires for a permit to hunt in any of the open management areas as long as the harvest quotas remain unfilled.
3. When the harvest quota is filled in any of the management areas, either by sport hunting or by depredation harvest, that area will be closed to mountain lion hunting, and no further permits will be issued for that area. Hunters holding a valid permit for a management area at the time that the harvest quota is filled will be notified by the Department that the area is closed, and that their permit is no longer valid. Hunters may then reapply for any other management area where the harvest quota has not been filled.

4. Department representatives will retain final judgement on issuance of permits and distribution of hunters in order to preclude a harvest quota or the over-loading of hunters in any one management area.
5. Unless otherwise specified by regulation of the Commission or Title 45 of NRS, any resident of Nevada, nonresident or alien is eligible to apply once for a mountain lion tag in any year.
6. A person who harvests a mountain lion shall, within 72 hours after harvesting it, present the skull and hide to a representative of the Department of Wildlife for inspection. The representative shall affix the seal of the Department permanently to the hide. It is unlawful for any person to transport such a hide from this state without a seal permanently affixed to the hide.
7. Except as provided in subsection 2, it is unlawful to possess the hide of a mountain lion without a seal permanently attached to it.
8. If a mountain lion is accidentally trapped or killed, the person trapping or killing it shall report the trapping or killing within 48 hours to a representative of the Department of Wildlife. The animal must be disposed of in accordance with the instructions of the representative.

1982

Limit: One.

Sex/Age Class: Either sex.

Hunting Hours: Any time of the day or night.

Season Dates:

October 1, 1982 through September 30, 1983, except as provided in sections 5 and 6 of this regulation.

Tag Quota: Unlimited.

Harvest Quota:

The harvest quota is the allowable harvest for each listed management area. When the harvest quota has been filled in any management area that area will be closed to hunting.

<u>Area</u>	<u>Objective</u>	<u>Area</u>	<u>Objective</u>
1	0	14	6
2	0	15	5
3	3	16	6
4	5	17	3
5	3	18	9
6	6	19	6
7	8	20	10
8	13	21	6
9	7	22	3
10	8	23	3
11	6	24	3
12	6	25	3
13	5	26	2
Total			135

Special Regulations

1. There is no quota on the number of tags that will be issued for the mountain lion management areas.
2. Tags will be available to residents and nonresidents by application only.
3. Hunters who are awarded tags for this mountain lion hunt must secure a hunting permit before they can hunt under the authority of this tag in any single management area. A valid lion hunting permit and tag must be in possession while hunting mountain lion.
4. Hunting permits will be authorized by mail, telephone, or by appearing in person only at the following department offices:

For Management Areas 3, 4, 12, 13, 14 and 15:
Region I Office, 380 W. "B" Street, Fallon, Nevada 89406
(702) 423-3171

For Management Areas 5, 6, 7, 8, 9, 10, 11, 19 and 20:
Region II Office, 1375 Mountain City Highway, Elko, Nevada 89801
(702) 738-5332

For Management Areas 16, 17, 18, 21, 22, 23, 24, 25 and 26:
Region III Office, 4747 Vegas Drive, Las Vegas, Nevada 89109
(702) 385-0285
5. Hunting permits will be valid in the specified management area until the harvest objective for that management area is reached, or the general season closure, whichever is first. Upon attainment of the harvest objective, the management area will be closed to lion hunting.
6. Hunters holding a valid permit for a management area at the time that the harvest objective is filled will be notified by the Department that the area is closed and that their permit is no longer valid. Hunters may then reapply for any other management area where the harvest objective has not been filled.
7. Department representatives in the Fallon, Elko and Las Vegas Offices will retain final judgement on issuance of permits and distribution of hunters.
8. A hunting permit may be invalidated by the Department and reissued for another mountain lion management area.

Ursus americanus

ABSTRACT

Landscape features such as rivers, mountains, desert basins, roads, and impermeable man-made structures may influence dispersal and gene flow among populations, thereby creating spatial structure across the landscape. In the US–Mexico borderland, urbanization and construction of the border fence have the potential to increase genetic subdivision and vulnerability to isolation in large mammal populations by bisecting movement corridors that have enabled dispersal between adjacent Sky Island mountain ranges. We examined genetic variation in black bears (*Ursus americanus*) from three regions in central and southern Arizona, US, to assess genetic and landscape connectivity in the US–Mexico border Sky Islands. We found that the three regions grouped into two subpopulations: the east-central subpopulation comprised of individuals sampled in the central highland and high desert regions, and the border subpopulation comprised of individuals sampled in the southern Sky Islands. Occupancy for the border subpopulation of black bears was influenced by cover type and distance to water, and occupancy-based corridor models identified 14 potential corridors connecting border Sky Island habitat cores with the east-central subpopulation. Biological quality of corridors, defined as length:width ratio and proportions of suitable habitat within corridors, declined with Sky Island dispersion. Our results show that black bears in the border subpopulation are moderately isolated from the east-central subpopulation, the main population segment of black bears in Arizona, and that connectivity for border bears may be vulnerable to anthropogenic activities, such as those associated with urbanization and trans-border security.

1. Introduction

Habitat connectivity across a landscape is important to ensuring the persistence of populations through the maintenance of gene flow (Vos et al., 2001), metapopulation dynamics (With et al., 1997), and demographic rescue (Tallmon et al., 2004). Without connectivity, habitat fragmentation constrains animal dispersal and threatens biological diversity (Johnson et al., 1992; Woodroffe and Ginsberg, 1998). Through time, habitat fragmentation yields small isolated populations with elevated extinction probabilities (Lande, 1988; Hanski, 1999). This is particularly true in landscapes where geography leads to spatial structuring of populations, such as large carnivores in the Sky Island (i.e., montane mountain

ranges) region of the Sonoran and Chihuahuan deserts of southwestern US and northern Mexico.

In human-dominated landscapes, connectivity is often maintained through corridors (Beier and Noss, 1998). Yet corridors may not be sufficient to facilitate population viability if they do not maintain both structural and functional connectivity. Structural connectivity describes the degree to which habitat patches are contiguous or physically linked to one another (With et al., 1997; Tischendorf and Fahrig, 2000), while functional connectivity explicitly incorporates the behavioral responses of animals to describe how both habitat and non-habitat (i.e., matrix) patches influence movement (Taylor et al., 1993; Wiens, 2001). Decreases in patch size and increased isolation may decrease structural connectivity, but if the newly-created matrix patches do not discourage movement, then functional connectivity may remain high (Baguette and Van Dyck, 2007). By contrast, a landscape may be characterized by a high degree of structural connectivity but have diminished functional connectivity as a result of being bisected by a feature that limits movement by creating exceptional risk of

crossing (e.g., roads, rivers) or acts as a physical impediment (e.g., a fence) (Proctor et al., 2005; Hayward and Kerley, 2009). Detailed information on structural and functional connectivity of corridors is important for predicting their efficacy to conserve wildlife (Beier and Noss, 1998), especially in areas where species already occupy fragmented habitats.

Arizona's desert Sky Island mountain ranges encompass one of the most biologically diverse regions in the United States. Suitable habitat for many of the region's large carnivores, including black bears (*Ursus americanus*), mountain lions (*Puma concolor*), and jaguars (*Panthera onca*) is found in oak woodland and montane habitats separated by lowland desert. Rapid urbanization and the construction of the US–Mexico border fence have the potential to drive genetic subdivision in large mammal populations by severing corridors that historically enabled dispersal between Arizona and Mexico Sky Island ranges (Flesch et al., 2010). Black bears in the region rely heavily on food resources found in these higher elevation montane habitats. The spatial dispersion of montane habitat has likely served to historically subdivide black bear populations, creating detectable genetic structure driven by infrequent, long-distance movements across desert basins (McRae et al., 2005; Onorato et al., 2004). Thus, desert black bears are an ideal candidate for modeling connectivity.

In this study, we integrated landscape genetics with occupancy modeling to assess landscape connectivity for black bears in southern Arizona's desert Sky Islands. Our objectives were to (i) assess genetic connectivity between black bears along the border with Sonora, Mexico, and the main population segment in east-central Arizona, and (ii) identify potential corridors linking core black bear habitats in the border Sky Island ranges. For the former objective, we hypothesized that bears along the border were genetically isolated from east-central bears. For the latter objective, we expected corridor quality to decline as the distance between linked core habitats increased.

2. Methods

2.1. Study areas

We sampled black bears from several sites in east-central and southern Arizona (Fig. 1). East-central sites were located in the central highlands north of the Mogollon Rim and the high desert immediately south of the Rim, where black bear habitat is relatively continuous (Fig. 1). The central highlands site was contained mostly within the White Mountains of the Apache-Sitgreaves National Forest, approximately 230 km east of Phoenix, Arizona (Fig. 1). The area was characterized by rugged terrain with steep slopes and deep canyons, an elevational gradient ranging from 1300 to 3000 m, and Rocky Mountain montane and subalpine habitat associations (Brown and Lowe, 1974). Areas above 1700 m were predominantly comprised of Engelmann spruce (*Picea engelmannii*) and subalpine fir (*Abies lasiocarpa*). Douglas fir (*Pseudotsuga menziesii*), white fir (*Abies concolor*), and blue spruce (*Picea pungens*) associations between 2400 and 2750 m; ponderosa pine (*Pinus ponderosa*), Gambel oak (*Quercus gambelii*), and aspen (*Populus tremuloides*) occur at lower-elevations (<2400 m). The central highlands encompassed a major portion of the watershed providing water to the Phoenix metropolitan area (population 4,192,887) via the Salt and Gila rivers. Yearly precipitation averaged 192 cm, most of which came during the winter as snowfall. Average daily temperatures ranged from 28 °C in July to –12 °C in December (NOAA, Western Regional Climate Center). Predominant land use within the area included timber production, livestock grazing, and recreation. Human population density for the area was 2.39/km², and housing density was 1.08/km² (<http://quickfacts.census.gov/qfd/states/04000.html>; accessed 29 June 2011).

The site south of the Mogollon Rim (hereafter referred to as the Tonto site) was located almost entirely within the Tonto National Forest (Fig. 1). The Tonto site was approximately 81 km east of Phoenix and 18 km west of Globe (population 7532), the nearest urban center. Elevations in the area ranged from 700–2300 m, with lower elevations characterized by gently sloping terrain and higher elevations having steep, rocky topography with slopes >45° (Cunningham et al., 2003). Primary vegetation at lower elevations was desert scrub and grassland (<900 m) and interior chaparral (900–1850 m) (Brown and Lowe, 1974). Madrean evergreen woodland (e.g., Gambel oak, Emory oak [*Quercus emoryi*], and ponderosa pine) occurred at higher elevations (>1850 m; Brown and Lowe, 1974). Yearly precipitation averaged 63 cm, most of which came during the summer (July and August) monsoons. Average daily temperatures ranged from 37 °C in July to –1 °C in December (NOAA, Western Regional Climate Center). Predominant land use within the area included livestock grazing and recreation. Human population and housing densities were 4.17/km² and 2.28/km², respectively, for the greater area (<http://quickfacts.census.gov/qfd/states/04000.html>; accessed 29 June 2011).

At the southern site (hereafter referred to as the border site), samples were collected from six Sky Island mountain ranges (i.e., Patagonia and Huachuca [wildland block 3], Whetstone [wildland block 4], Rincon [wildland block 9], Galiuro [wildland block 11], and Chiricahua [wildland block 7] mountains; Fig. 2), north of the border with Sonora, Mexico, and mostly located within the Coronado National Forest. The border site was mostly southeast of the Tucson metropolitan area (population 980,263); the most intensive sample collection occurred in wildland block 3, 83 km southeast of Tucson and directly adjacent to the town of Sierra Vista (population 43,044) and Fort Huachuca military base (Fig. 1). Elevations at the border site ranged from 1300 to 3000 m, with the lowest elevations (<1370 m) characterized as desert basin primarily comprised of catclaw acacia (*Acacia greggii*), creosote (*Larrea tridentata*), and mesquite (*Prosopis glandulosa*) (Wallmo, 1955). Desert shrub and grassland associations occurred at elevations between 1370 and 1524 m, oak woodlands occurred between 1524 and 2130 m, depending on specific site characteristics, and Madrean evergreen woodland generally occurred at elevations >1800 m (Wallmo, 1955). Yearly precipitation averaged 39 cm, most of which came during the summer (July and August) monsoons. Average daily temperatures ranged from 35 °C in July to 0.5 °C in December (NOAA, Western Regional Climate Center). Predominant land use for the area includes livestock grazing and recreation. The distribution of black bear habitat at the border site was discontinuous and constrained to Sky Island mountain ranges (Fig. 1). The human population (9.62/km²) and housing densities (3.85/km²) for the greater border area were the highest of the three sampling sites (<http://quickfacts.census.gov/qfd/states/04000.html>; accessed 29 June 2011).

The Patagonia–Huachuca and Tumacacori (i.e., wildland block 1; Fig. 2) wildland blocks straddled the Arizona–Sonora border, while all other wildland blocks included in connectivity analyses occurred entirely within Arizona. The Patagonia and Huachuca mountains extended approximately 31 km and 4 km, respectively, into Sonora, with the Patagonia Mountains separated by 7 km from the northern extent of the large (≈5396 km²) Sierra Mariquita–Sierra de los Ajos mountain range complex (Fig. 2). The Tumacacori wildland block extended 5 km into Sonora and the southern-most extent was within 7 km and 19 km, respectively, of the Sierra Cibuta and Sierra de Pinitos mountains (Fig. 2). Vegetation in northern Sonora mirrored that of southern Arizona, with shrub and grassland associations at lower elevations, oak woodlands at mid-elevations, and Madrean evergreen woodlands at higher elevations (Brown, 1994; Bahre and Minnich, 2001). Predominant land use in northern Sonora was livestock grazing (Vasquez-Leon and Liverman, 2004). The international boundary between Arizona and So-

Huachuca, (9) Bisbee, (10) Douglas, and (11) Nogales.

nora, Mexico, spans nearly 600 km, approximately 70% of which was fenced. The type of fence structure varies along the border (Fig. 1). Some segments were ≥ 4 m tall with either no openings or vertical gaps 5–10 cm wide and thus impermeable to most medium- and large-bodied mammals, while other sections consisted of 4–6 strands of barbed wire coupled with “Normandy style” cross-bar vehicle barriers (United States Customs and Border Protection, 2009), and were relatively permeable.

2.2. Black bear distribution and status in Arizona and Sonora, Mexico

In Arizona, black bears were classified as a game species and were hunted during the spring and fall. Season lengths and harvest limits varied by game management unit (GMU), with all units being closed for the season when the female harvest approximated

10% of the estimated female population in the unit. For GMU in the border sampling area, harvest limits were conservative and generally range from 1–3 females/GMU/yr. Black bears in Mexico were classified as “endangered of extinction” in 1986, and hunting seasons were closed indefinitely (Doan-Crider and Hellgren, 1996). Over the last several decades, the historical distribution of black bears in Mexico is believed to have been reduced by 20% due to habitat loss, poaching, and illegal trade (Doan-Crider and Hellgren, 1996; Sierra-Corona et al., 2005). Relatively little is known about the status of black bears in Sonora. Sierra-Corona et al. (2005), working in the Sierra de San Luis in northeastern Sonora (Fig. 2; wildland block 21), found that bear density was low compared to similar areas on either side of the border (e.g., Coahuila, Mexico: Doan-Crider, 1995; east-central Arizona: LeCount, 1982), but did not comment on possible reasons.

2.3. Sample collection and genetic analyses

We collected hair samples from black bears using hair-snags and hair and tissue from mandatory hunter check-in. We deployed two hair-snag sampling grids, one at the border site in the Huachuca and Patagonia mountains (i.e., Huachuca–Patagonia grid; wildland block 3), and one in the central highlands (i.e., White Mountains grid) (Fig. 1). The Huachuca–Patagonia and White Mountains grids consisted of 67 and 74 grid cells (4×4 km), respectively. Sixty-three percent of the Huachuca–Patagonia grid was comprised of evergreen habitat associations, 23% was desert shrub and grassland, and the remaining 9% was oak woodland. For the White Mountains grid, 79% was comprised of evergreen habitat associations, 13% was montane shrub and grassland, and the remaining 8% was deciduous woodland. In each cell, we built a hair-snag “corral” by running a single strand of barbed wire at a height of approximately 45 cm around several trees (Woods et al., 1999). We chose hair-snag locations based on black bear

sign, natural travel routes, and forage availability, and maintained a minimum distance of 2 km between hair-snags located in adjacent cells. We baited the center of corrals with 1L of aged fish oil, and ran 3, 10–14 d capture sessions from May through September. The use of a single lure and a standard volume should control for lure-induced heterogeneity in habitat-specific detection probabilities (MacKenzie et al., 2006). We used forceps to collect hair samples from barbs, stored individual samples in tooth envelopes, and flamed barbs to prevent cross-contamination. Samples also were obtained at the high desert site from hair-snags located in the Tonto National Forest that were independently deployed and operated by Arizona Game and Fish Department (AGFD) personnel (Fig. 1). The Tonto hair-snags were deployed opportunistically rather than in a grid-design, which precluded their use in estimating a site density.

We extracted DNA from samples using a Qiagen DNeasy Blood and Tissue Kit (Qiagen) employing an ammonium acetate protocol (modified from the PUREGENE kit; Gentra Systems). We used a set

of 11 microsatellite loci known to amplify in black bears (G10J, G10M, G10X, G10B, G10H, G10C, G10L, G1D, G1a, UarMu50, UarMu59; Paetkau et al., 1995, 1998) grouped into three sets based on product size and primer label. Each set of loci was amplified together in the same Polymerase Chain Reaction (PCR) in 10 μ L PCRs using a Master-cycler ep gradient (Eppendorf) and 3 μ L of template DNA, 0.2 mM of each dNTP, 0.2 M to 0.4 M of each primer pair, 1 U of *Taq* DNA polymerase (NEB), 1.25 mM $MgCl_2$ and 2 \times reaction buffer (10 mM Tris–HCl, 50 mM KCl, 0.05 mg/mL BSA). Amplification conditions were 94 °C for 2 min, then 94 °C for 30 s, 60 °C for 30 s, 72 °C for 30 s for 35 cycles, then 72 °C for 10 min and a final extension at 60 °C for 45 min. Multiplexed reactions were combined with an internal lane size standard and electrophoresed through a capillary gel matrix using an ABI 3730 Automated DNA Sequencer. Allele sizes were determined for each locus using GeneMapper software v3.7 (Applied Biosystems).

We ran positive and negative controls within each genotyping set and included an individual of known genotype at each locus within every sample set analyzed to maximize quality and consistency of genotyping. Each sample was amplified repeatedly until 3 matching genotypes were obtained at each locus within each individual, or until we ran out of DNA, to avoid errors associated with DNA collected with non-invasive methods (Taberlet et al., 1996, 1999; Kohn and Wayne, 1997). This resulted in the generation of at least three multilocus genotypes for each sample.

For sex determination, a fragment of the amelogenin gene was amplified using the primers SE47 and SE48 (Ennis and Gallagher, 1994). The amplification conditions were similar to those used for the microsatellites except the annealing temperature was 64 °C and the annealing and extension times were decreased to 15 s per cycle. PCR products were run on a 2% agarose gel stained with ethidium bromide. Samples were scored as female if they exhibited one band and males if there were two bands. DNA samples extracted from the tissues of known-sex harvested black bears were used as controls for our sexing assessments.

The program GIMLET (Valiere, 2002) was used to generate a consensus multilocus genotype for each sample and to identify matching multilocus genotypes among samples. Samples with genotypes for at least 6 loci were retained in the dataset; loci that did not have three matching genotypes were scored as “missing data.” Only unique multilocus genotypes were included in subsequent analyses of basic population genetic parameters for the overall dataset. We calculated the number of alleles per locus, observed heterozygosity (H_O), and expected heterozygosity (H_E) for each locus using GDA (version 1.1, Lewis and Zaykin, 1999). Tests for linkage disequilibrium and deficiencies of heterozygotes relative to Hardy–Weinberg expectations for each locus and globally were performed using the program GENEPOP (version 3.4; Raymond and Rousset, 2000). We employed two Bayesian clustering software programs, STRUCTURE (version 2.2, Pritchard et al., 2000) with the ΔK method (Evanno et al., 2005) and GENELAND (version 3.1.4, Guillot et al., 2005b), to infer the number of subpopulations in our dataset and assign individuals to those subpopulations. All samples with unique multilocus genotypes were used in the STRUCTURE analysis, whereas only those samples with both unique multilocus genotypes and spatial coordinates were used in the GENELAND analysis.

In STRUCTURE we performed five runs at each value of K (the number of subpopulations) from $K = 1$ to $K = 10$. Each run consisted of 100,000 replicates of the MCMC after a burn-in of 30,000 replicates. We used the admixture model and allowed the allele frequencies to be correlated among subpopulations. To assign individuals to subpopulations, a final run (100,000 burn-in and 500,000 replicates) at the inferred K was performed. The values of q , which are indicative of the proportion of an individual's genome characteristic of each subpopulation, were used to assign indi-

viduals. Individuals were considered unambiguously assigned to a subpopulation when q values were greater than 0.75. When q values were less than 0.75, assignments of individuals were distributed among multiple subpopulations. To infer the number of subpopulations (K) in GENELAND, we first varied the number of subpopulations from 1 to 5 using 5000 stored MCMC iterations (200,000 iterations, thinning = 40). We set the maximum rate of the Poisson process to 100 (a value close to the number of individuals in our data set) and the maximum number of nuclei to 300 ($3 \times$ maximum rate as suggested by Guillot et al., 2005a). We ran the GENELAND MCMC 10 times with the level of uncertainty attached to our spatial coordinates set to 2 km. We used the mode of the distribution of K as a point estimate of K . The assignment of individuals to subpopulations was performed in a separate run as suggested by Guillot et al. (2005a). For this run, K was set to the inferred number of subpopulations and all other parameters were similar to those runs with variable K . The posterior probability of subpopulation membership was computed for each pixel of the spatial domain (50×50 pixels), using a burn-in of 1000 iterations. Individuals with a posterior probability of population membership of greater than 0.75 were unambiguously assigned to that subpopulation.

For each subpopulation inferred in either STRUCTURE or in GENELAND, levels of genetic diversity were estimated by calculating the average number of alleles per locus, observed heterozygosity (H_O), expected heterozygosity (H_E), fixation index, and the number and frequency of unique alleles using GDA. We estimated the levels of genetic differentiation among the inferred subpopulations by calculating F_{ST} in GDA. Significance of each F_{ST} value was based on 95% confidence intervals determined by bootstrapping across all loci, where confidence intervals bracketing zero indicate no evidence of genetic variance partitioning between sample set pairs. Average relatedness of individuals within each subpopulation was assessed using Wang's (2002) estimator in SPAGeDi (Hardy and Vekemans, 2002).

The program CAPWIRE (Miller et al., 2005) was used to estimate population size within the Huachuca–Patagonia and White Mountains grids. We set the maximum population size to 100 for the Huachuca–Patagonia grid and 400 for the White Mountains grid, and used the likelihood ratio test (LRT) to determine which capture probability model was most accurate. Two capture models are available: the even capture probability model (ECM) where every individual is equally likely to be captured and the two innate rates model (TIRM) where individuals do not display equal capture probabilities. The appropriate model, based on LRT, was then used to estimate population size for each of the two grids.

2.4. Occupancy and landscape modeling

For occupancy analyses, our objective was to determine if bear occupancy (ψ) at the border hair-snap grid (i.e., Huachuca and Patagonia mountains) differed relative to habitat type and landscape covariates. We used the occupancy model option in program MARK (White and Burnham, 1999) to estimate occupancy relative to land cover (Madrean evergreen woodland [MEW], mixed conifer woodland [MXC], semi-desert grassland [DG], plains and Great Basin grassland [GBG], and oak woodland [OW]), slope ($^\circ$), aspect, elevation (m), and distances to permanent water and roads (m). We used point extraction and Euclidean distance routines in a 30-m resolution (i.e., USGS Seamless Server NED data) GIS to collect information on land cover and landscape covariates for hair-snap locations. We tested for collinearity among potential variables by examining tolerance and variance inflation factors (VIF) using weighted least squares regression, and excluded variables with tolerance scores <0.4 from analyses (Allison, 1999).

We formulated 12 models and kept the detection probability (p) constant, assuming it did not vary across time or habitat types and was not influenced by individual covariates. We modeled occupancy (ψ) with and without a habitat effect (i.e., group effect) or individual covariates. We used the variance inflation factor (i.e., c -hat in MARK) to guard against overdispersion and the small sample size correction of Akaike's Information Criterion (QAICc). C -hat was calculated using the median c -hat procedure in program MARK. In addition to reporting model selection results, we also reported the beta parameter and 95% confidence interval for the covariates and evaluated whether or not the beta parameter overlapped zero and used this as further evidence of the significance of each individual covariate for modeling occurrence of bears. We calculated model-averaged occupancy values and 95% confidence intervals for the model averaged parameters following procedures in program MARK.

Corridor modeling involved four steps: (i) creating a habitat suitability model; (ii) identifying breeding- and population-size patches within Sky Island wildland blocks (i.e., polygons estimating the areal extent for each Sky Island range; Fig. 1); (iii) creating a cost surface representing the grid cell resistance to movement; and (iv) applying a cost-distance routine to identify pixel swaths (i.e., corridors) linking wildland blocks. We used the results of the border occupancy model to parameterize a habitat suitability model (HSM) for the composite sampling region (i.e., 15 mountain ranges [four of which were combined into two wildland blocks] comprising the sky island complex and 1 mountain range [Pinal Mountains; wildland block 14] representing the southern extent of the high desert sampling region; Fig. 2). The HSM was comprised of grid layers representing land cover, elevation, aspect, slope, distance to water, and distance to road. For all grids we reclassified pixel values using the results from the occupancy models. Distances to road and water were weakly correlated (i.e., tolerance <0.4), but because it has been documented that bears avoid roads (e.g., Brody and Pelton, 1989), we included a reclassified road grid in our HSM.

We reclassified the land cover grid by collapsing 35 landcover classes from the 2001 National Landcover Data (NLCD) set (e.g., Encinal oak woodland) into five broader categories (e.g., oak woodland) and assigning the latter a value from 0 (absolute non-habitat) to 100 (optimal habitat) based on detection probabilities scaled from occupancy models (Table 1). For the elevation, aspect, and distances to water and roads grids, we created 5, 4, 3, and 3 evenly-spaced bins, respectively, and assigned values (0–100) based on probabilities of occurrence at hair-snag stations (Table 1). Slope often is modeled as a discrete value for individual grid pixels. While convenient, that practice may fail to capture neighborhood permeability thresholds that can occur in a rugged landscape, such as the Sky Island region. Accordingly, we used a moving window analysis in a GIS where we characterized the topographic position of a given pixel relative to adjacent pixels found within a 200-m radius. Using this method, we classified pixels as canyon bottom if the focal pixel elevation was at least 12 m less than the neighborhood average, a ridge-top if the pixel elevation was at least 12 m greater than the neighborhood average, a gentle slope if the pixel was neither a canyon bottom nor a ridge-top and had a slope $<6^\circ$, and a steep slope if the pixel was neither a canyon bottom nor a ridge-top and had a slope $>6^\circ$. The resulting topographic position index (TPI) grid was then reclassified following the method used for the elevation grid but using three bins. Finally, we combined the six individual grids using a weighted geometric mean algorithm (Table 1) where individual grid weighting factors were scaled to their proportional contribution based on the model-averaged Akaike weights.

We used the HSM to identify contiguous areas of suitable habitat that could function as breeding- and population-size patches

Table 1

Grid layers and variables, reclassified grid cell values, weighting factors used to assemble the habitat suitability model for the Arizona border Sky Islands.

Variable	Reclassified cell value	Weighting factor
<i>Land cover type</i>		0.50

Gentle slope	100	
Ridge top	25	

within wildland blocks. Based on previous black bear work conducted in Arizona, we selected a minimum breeding patch size of 50 km² and extrapolated a minimum population patch ($n = 50$ bears) size of 300 km² (LeCount, 1982). We used a moving window analysis (200-m radius) in a GIS to group together pixels with a suitability value of ≥ 60 into the breeding and population patches. We chose the 200-m radius to depict suitability relative to the landscape pattern and the spatial requirements and perceptual ability of black bears (Vos et al., 2001). The Sky Island landscape is relatively patchy in nature, owing to the basin and range topography, and the window analysis must be fine enough to detect changes in patch quality at a scale that bears are likely to perceive (Lima and Zollner, 1996). Cunningham and Ballard (2004) found that the home ranges of female black bears in central Arizona's Sky Islands averaged 13 km². Our 200-m radius equates to a 12.6 ha neighborhood, which is approximately one-tenth the area of the average female home range, and should represent a patch size that bears can detect.

We converted the HSM into a cost surface by calculating cell resistance (i.e., travel cost; cell resistance = 100 – pixel suitability) for the entire grid. The resulting cost surface grid was comprised of pixel values that reflected the cost of (or resistance to) movement through each individual grid cell, with increasing cell values representing increasing resistance to movement. We then applied a moving window analysis (200-m radius) to generate corridor models (pixel swaths) that connected habitat cores while minimizing resistance to movement. We selected the best biological corridors (e.g., Bennett et al., 1994) based on the pixel swath that minimized within-swath gaps, maximized within-swath habitat suitability, and reduced edge effects by maintaining a minimum width equal to the radius of an estimated home range (LeCount, 1982; Cunningham and Ballard, 2004). All habitat and corridor modeling was done using the CorridorDesigner package for ArcGIS (Majka et al., 2007).

Table 2

Characterization of the 11 microsatellite loci used in genetic analyses of black bears sampled at central highlands and border sites in Arizona, 2007–2008. Number of samples genotyped (*N*), number of alleles per locus (*A*), expected (H_E) and observed (H_O) heterozygosities and the fixation index are reported.

Locus	<i>N</i>	<i>A</i>	H_E	H_O	<i>f</i>

^a Significant heterozygote deficiency ($\alpha = 0.05$).

3. Results

3.1. Genetic connectivity

Samples for genetic analyses were distributed over $\approx 31,250 \text{ km}^2$ in the east-central region and collected from six Sky Island mountain ranges (Fig. 1). For the White Mountains hair-snag grid, samples were collected from 43% of grid cells, with 35% of those hair-snags yielding samples from ≥ 2 capture sessions. Similarly, samples were collected from 40% of grid cells at the border hair-snag grid, with 46% of those hair-snags yielding samples from ≥ 2 capture sessions. We were able to obtain usable

multilocus genotypes for 189 of the 258 samples. Of these 189 multilocus genotypes, 158 were identified by GIMLET as being unique. Of these 158 individuals, 52 were female and 96 were male (10 of unknown sex). For the pooled sample, the overall number of alleles per locus ranged from 3 (UarMu50) to 10 (G10H) and observed single locus heterozygosities ranged from 0.083 (UarMu50) to 0.790 (G10L) (Table 2). Global tests of the pooled dataset revealed an overall significant deviation from Hardy–Weinberg equilibrium ($P = 0.003$) and significant deficiencies of heterozygotes at three individual loci were observed, which is not unexpected if there is underlying population subdivision within the pooled dataset (Table 2). Linkage disequilibrium was observed between three pairs of loci (G1D–G10B, G1D–G10L and G1D–G10J) after a sequential Bonferroni correction ($\alpha = 0.00019$). Assuming matching multilocus genotypes indicate re-captures, 138 bears were captured only once, 13 bears were captured twice, four were captured three times, two were captured four times, and one was captured five times. In each instance where the data indicated that a bear was recaptured multiple times, all recaptures for that individual occurred within the same grid used for population estimation or within the set of individuals that could not be assigned to a grid. In only four instances did the multilocus genotypes of pairs of unique individuals differ at less than three loci.

STRUCTURE and the ΔK measure indicated the most likely number of subpopulations (K) was 3 (Fig. 3a); however at $K = 3$ few individuals were assigned to any of the three subpopulations with high certainty. When $K = 2$, most individuals were unambiguously assigned to one of two subpopulations (Fig. 3b). These two subpopulation groupings roughly corresponded to the east-central ($n = 102$; 62 males, 38 females, 2 unknown sex) and border ($n = 33$; 17 males, 11 females, 5 unknown sex) regions. Twenty-

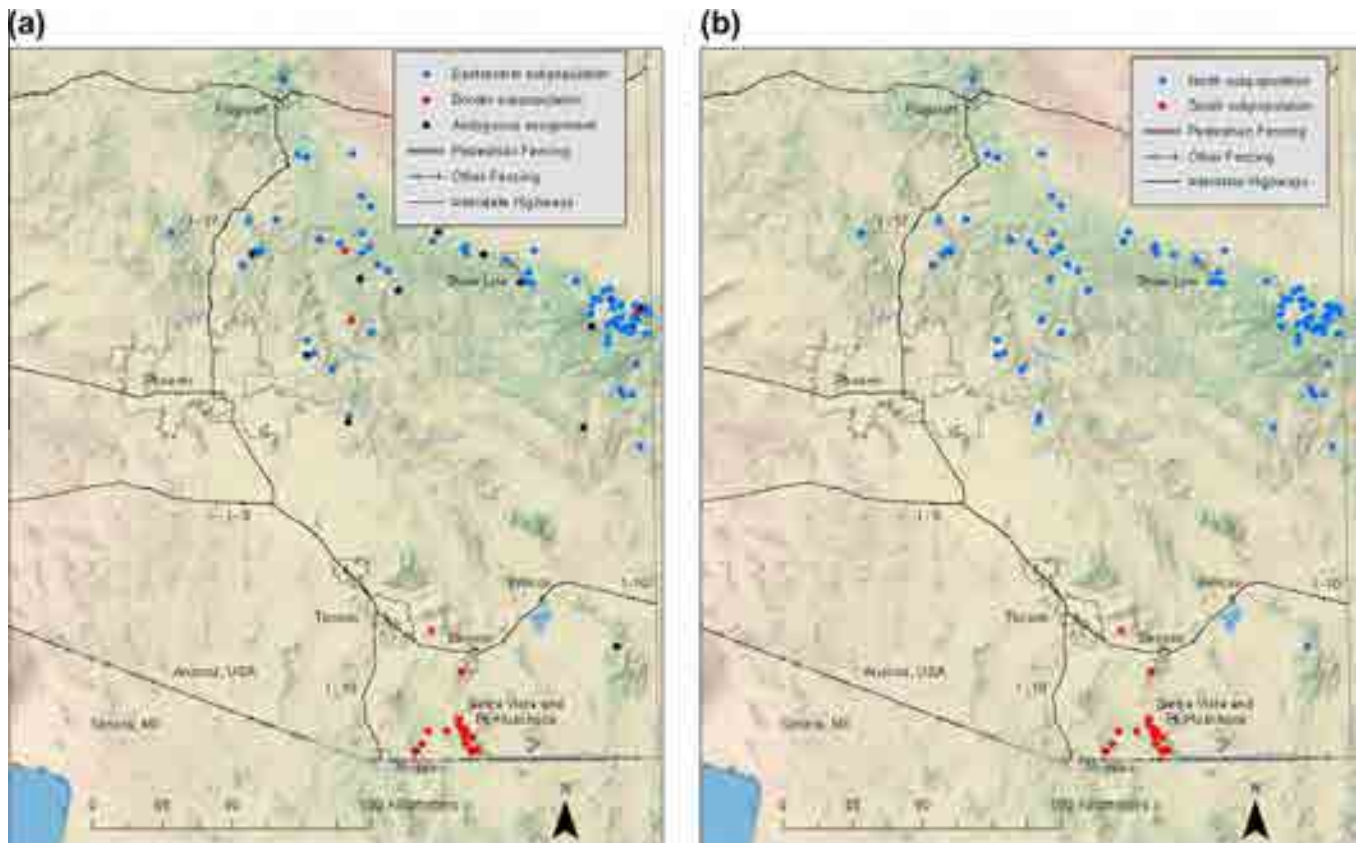

Fig. 3. (a and b) Subpopulation assignments of black bears sampled in Arizona. Assignments were based on genetic information using the programs structure (a) and Geneland (b).

Table 3

Estimates of genetic diversity for the two subpopulations identified from black bears sampled at central highlands and border sites in Arizona, 2007–2008. Number of samples genotyped (N), average number of alleles per locus (A), expected (H_E) and observed (H_O) heterozygosities, fixation index (f) values, and (F_{ST}) are reported.

Population	N	A	H_E	H_O	f	F_{ST}
Overall	158	6.3	0.534	0.508	0.048	NA
East-central ^a	102	5.8	0.541	0.538	0.006	0.111
Border ^a	33	4.3	0.432	0.422	0.023	
East-central ^b	113	6.2	0.540	0.534	0.011	0.113
Border ^b	28	3.9	0.411	0.401	0.024	

^a Subpopulations assigned by STRUCTURE. Twenty-three bears with ambiguous assignments were removed from the dataset.

^b Subpopulations assigned by GENELAND.

three individuals (17 males, 3 females, 3 unknown sex) were assigned to both subpopulations (q values less than 0.75): 19 of the individuals were from the central highlands area, 3 were from the high desert area, and one was from the border area. These ambiguously assigned individuals were not included in the subsequent genetic or demographic analyses of the inferred subpopulations. Similar levels of genetic diversity were observed within each of the two subpopulations defined by STRUCTURE (Table 3). There were large numbers of unique alleles in the east-central subpopulation ($n = 22$) compared to the border subpopulation ($n = 5$). Most unique alleles were at low frequency, however at 1 locus (G1D in the border subpopulation) a unique allele was observed at a frequency of 41%. Significant genetic differentiation was observed between the two inferred subpopulations ($F_{ST} = 0.111$; 95% CI: 0.056–0.156; $n = 135$; Table 3). Average relatedness estimates of individuals within subpopulations were 0.16 and 0.37 in the central highlands and border subpopulations, respectively.

The GENELAND analysis indicated that the most likely number of subpopulations was 2. Through the incorporation of spatial coordinates, GENELAND was able to identify a northern subpopulation ($n = 113$, 70 males, 37 females, 6 unknown sex) and a southern subpopulation ($n = 28$, 15 males, 10 females, 3 unknown sex) which corresponded to the east-central and border regions of our study. All individuals were unambiguously assigned to one of the two subpopulations. Similar levels of genetic diversity were observed within each of the two subpopulations defined by GENELAND (Table 3). There were large numbers of unique alleles in the east-central subpopulation ($n = 26$) compared to the border subpopulation ($n = 1$), however most unique alleles were at low frequency. Significant genetic differentiation was observed between the two inferred subpopulations ($F_{ST} = 0.113$; 95% CI: 0.051–0.167; Table 3). Average relatedness estimates of individuals within subpopulations were 0.16 and 0.41 in the east-central and border subpopulations, respectively.

Table 4

Models of black bear occupancy for the Border grid (Huachuca and Patagonia mountains) in southern Arizona. We held detection probability constant [$p(\cdot)$] and modeled occupancy (ψ) with and without a group effect (i.e., differences between habitat types) and with five site specific covariates (aspect, distances to water [disw] and roads [disroad], elevation [elev], and slope). We present all models, QAICc, model weight, number of parameters (k), and beta values of individual covariates with corresponding 95% confidence intervals. Cells shaded gray had beta values with 95% confidence intervals not overlapping zero, providing evidence of significance.

Model	QAICc	Model weight	k	Covariate beta value	Lower95% CI	Upper95% CI
$p(\cdot) \psi[(\text{group}) + (\text{water})]$	198.7	0.45	7	−0.003	−0.006	−0.0001
$p(\cdot) \psi[(\cdot) + (\text{water})]$	200.8	0.16	3	−0.004	−0.006	−0.001

Table 5

Occupancy (ψ) estimates of black bears in different habitat types at Border study site in Arizona. Estimates were generated in program MARK by model averaging values of ψ over the suite of candidate models presented in Table 4.

Habitat type	ψ	SE	Lower95% CI	Upper95% CI
Madrean evergreen (MEW)	0.72	0.10	0.50	0.87
Mixed conifer (MXC)	0.55	0.17	0.25	0.83
Desert grassland (DG)	0.45	0.25	0.10	0.86
Great Basin grassland (GBG)	0.10	0.23	0.001	0.94
Oak woodland (OW)	0.71	0.14	0.39	0.90

The LRT in CAPWIRE identified the TIRM as most appropriate capture probability model for data from the White Mountains grid and estimated the population size to be 252 bears (95% CI: 137–396). The ECM was identified as most appropriate capture probability model for data from the Huachuca–Patagonia grid and population size was estimated to be 69 bears (95% CI: 39–82).

3.2. Occupancy and connectivity modeling

For the border data set we estimated probability of detection to be 0.79 (SE = 0.04) and found strong evidence that occupancy differed between habitat types and that distance to water (disw) from hair-snags influenced estimates of occupancy (ψ). Models with a habitat effect (group effect) accounted for 85% of the weight (Table 4) and the individual covariate “disw” was in the top two models (accounting for 61% of the model weight), and was the only covariate whose 95% confidence interval around the beta value did not overlap zero (Table 4). Occupancy estimates ranged between 0.72 and 0.10 between habitat types with occupancy highest in MEW followed by OW, MXC, DG and GBG (Table 5). Variance was highest for DG and GBG indicating high levels of uncertainty in our estimates of occupancy for these habitat types. The relationship between distance to water and occupancy was negative.

The habitat suitability model identified population- and breeding-size patches of suitable and optimal habitat in all Sky Island wildland blocks (Fig. 4). Along the border, the greatest area of population- and breeding-size patches was found in the Chiricahua block (block 7; 923 km²), followed by the Huachuca–Patagonia (block 3; 831 km²), and Santa Rita (block 2; 481 km²) blocks (Fig. 4). The Dragoon Mountains block was the smallest and had the least amount of suitable habitat (Fig. 4, block 6; 307 km²). Isolation of wildland blocks generally increased from west to east, with the shortest nearest neighbor distances occurring between the Huachuca–Patagonia and Santa Rita blocks followed closely by the Huachuca–Patagonia and Tumacacori blocks. The structural and qualitative characteristics of potential corridors connecting

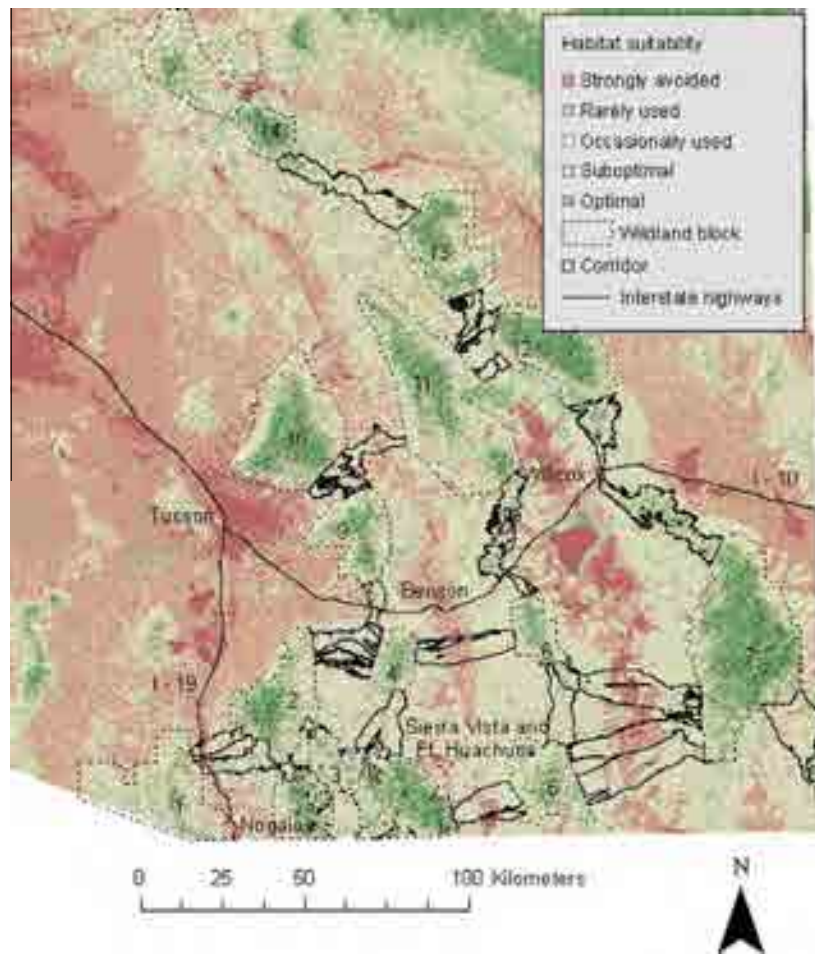

Fig. 4. Habitat suitability map for the area encompassing the Arizona Sky Island wildland blocks and corridors.

the eight border Sky Islands (wildland blocks 1–8; Fig. 5) differed greatly, but generally the western-most wildland blocks (i.e., Tumacacori [1], Santa Rita [2], Huachuca–Patagonia [3], and Whetstone [4] blocks) were connected by higher quality corridors. For these corridors, length to narrowest width ratios averaged $\leq 4.4:1$ (range: 1.11:1–9.0:1; SE = 0.95), with ≥ 1 corridor within each of the individual linkages containing $\geq 57\%$ suitable (either optimal or suboptimal) habitat (Fig. 4). By contrast, the mean length to width ratios of the corridors connecting the eastern-most wildland blocks (i.e., Mule [5], Dragoon [6], Chiricahua [7], and Peloncillo [8] blocks) was 6.8:1 (range: 1.2:1–12.1:1; SE = 1.11), and only 1 linkage (Dragoon–Mule mountains corridor) contained $>57\%$ suitable habitat (Fig. 4). The linkages connecting the Huachuca–Patagonia and Mule, Whetstone and Mule, Dragoon and Chiricahua, and Mule and Chiricahua blocks all contained $<57\%$ suitable habitat and spanned 23–44 km over desert basin habitat (Fig. 5). Corridors connecting the northernmost wildland blocks (blocks 9–14; Fig. 5) were generally of similar suitability to the western-most border wildland blocks in that all contained $>57\%$ of optimal or suboptimal habitat (Fig. 4), but length to width ratios were more variable ($\bar{x} = 4.7:1$; range: 1.0:1–17.0:1; SE = 2.08).

4. Discussion and conclusions

Our study revealed several important findings regarding black bear genetic and landscape connectivity in Arizona. First, we detected significant genetic differentiation between black bears sampled in the border region and those sampled in the high desert and

central highlands regions. Second, based on density estimates derived from the White Mountains and Huachuca–Patagonia hair-snag grids, the border subpopulation density (0.06 bear/km^2) was substantially lower than the east-central subpopulation (0.21 bear/km^2). Although our grid-based density estimates relate only to the area covered by the grids, the bio-physical characteristics of grids were very similar to their respective regions (Brown, 1994). Accordingly, we believe the estimated grid densities approximate densities across sampling regions. Finally, while the border Sky Island mountain ranges do provide adequate amounts of suitable habitat to support black bears, there is wide variation in the biological quality of corridors that connect them. While black bears are not a species of concern in US, they are in Mexico, which represents the southern extent of their historic and current range (Pelton et al., 1998). Given the above, black bear persistence in the US–Mexico border Sky Islands may be particularly vulnerable to further loss of habitat due to urbanization and border security activities.

Black bear populations in Arizona exhibit a north–south spatial structure in which the border sub-population is isolated from, and less genetically diverse than, the main population segment in east-central Arizona. These patterns are likely the result of both historic and contemporary impediments to individual movement and thus gene flow (McRae et al., 2005). For example, the harsh environment and dispersion of suitable montane habitat patches in a desert basin matrix have previously been implicated as historic impediments to large mammal gene flow (Onorato et al., 2004; McRae et al., 2005), and likely are complicit in the isolation we detected between the border and east-central subpopulations. Addi-

Fig. 5. Linkage design for the southern Arizona Sky Islands. The design represents land that, if conserved, should enhance the ability of black bears to move between wildland blocks.

tionally, it is feasible that Interstate Highways 10 and 19, the expanding human footprint near Tucson and other urban areas in southeastern Arizona, and the US–Mexico border fence represent contemporary impediments to movement and function to hasten genetic isolation of black bears in the border region. Indeed, there is a growing body of research indicating that urbanization and linear anthropogenic barriers can drive spatial structure in bear and other large carnivore populations (e.g., Kyle and Strobeck, 2001; Proctor et al., 2005; Burdett et al., 2010). Thus, while the desert basin has likely historically limited bear gene flow between the high desert and border regions, it is also likely that landscape fragmentation due to anthropogenic activities, including border security, has further limited gene flow.

Large carnivores are highly vagile, require a large amount of area to maintain a viable population and, as a result, are often highly vulnerable to habitat fragmentation (Weaver et al., 1996; Burdett et al., 2010) and loss of connectivity (Beckmann et al., 2010). Over the last few decades, central and southern Arizona

has experienced rapid human population growth (Primack, 2006); urban expansion in the Tucson metropolitan area alone is expected to increase by 22% over the next decade (Pima Association of Governments: www.pagnet.org/regionaldata/population/populationestimates/tabid/582/default.aspx). Our linkage design (Fig. 5) for Arizona's border Sky Islands provides a template for land-use managers and planners to prioritize conservation efforts where future development is most immediate and likely to adversely affect landscape connectivity. For example, we believe that conservation efforts aimed at protecting corridors within the Nogales–Sierra Vista–Tucson triangle should be prioritized. This area contains relatively high quality corridors linking wildland blocks (e.g., Tumacacori, Santa Rita, and Patagonia–Huachuca; Fig. 2) that either extend into Sonora, Mexico, or are immediately adjacent to Sonora wildland blocks (e.g., Sierra Cibuta, Sierra Pinito, and Sierra Chivato), thus providing the best opportunity for trans-border movement. Urbanization and additional stretches of the impermeable pedestrian fence along the international border have the po-

tential to threaten connectivity in an area that may be critically important in facilitating trans-border dispersal, ultimately predisposing segments (i.e., the more isolated Sky Island mountain ranges) of the low density border black bear subpopulation to localized extinction.

Populations of black bears in the southwestern US and northern Mexico appear to display a metapopulation structure (Onorato et al., 2004), thus a significant step in ameliorating effects of habitat fragmentation will be to maintain or restore landscape connectivity within the system. The results of our analyses identified opportunities and challenges to maintaining connectivity among border Sky Islands and to the high desert region. A central challenge is that structural connectivity (based on length:width and % suitable habitat metrics: Bennett et al., 1994) between border region wildland blocks varied considerably. Moreover, several adjacent wildland blocks that appear to benefit from sound structural connectivity also appear to be vulnerable to compromised functional connectivity due to increasing infrastructure. For example, the Tumacacori-Santa Rita corridor is bisected by Interstate Highway 19 (Fig. 5), which may degrade functional connectivity and reduce the likelihood of migrants from Sonora moving into the Sky Islands east of the interstate. Similarly, three other corridors (Whetstone-Rincon, Dragoon-Pinaleno, and Chiricahua-Pinaleno) potentially important in facilitating gene flow between the border and high desert regions, are bisected by Interstate Highway 10 (Fig. 5). These highway-corridor intersections would be ideal areas to target for road mitigation projects (e.g. road crossing structures designed specifically for black bears and other large mammals, see Beckmann et al., 2010) that enhance functional connectivity.

The US–Mexico borderland is one of the most biologically diverse and ecologically vulnerable regions in the United States (Cordova and de la Parra, 2007). Because rapid urbanization and border security activities threaten to alter the spatial structure of trans-border wildlife populations (Flesch et al., 2010), it is important to identify opportunities to maintain or restore borderland connectivity. We identified suitable habitat and movement corridors for black bears in the Sky Island mountain ranges of southern Arizona, information that can help inform systems-level approaches to land-use planning and conservation (Moilanen et al., 2005). Currently, in the western US, there is opportunity to integrate connectivity conservation with land-planning (Western Governor's Association, 2008). For example, land-use planners in the Tucson metropolitan area have developed a regional conservation plan with a specific focus on maintaining wildlife linkages and increasing the permeability of transportation corridors (see Campbell and Kennedy, 2010). The information we present here, if incorporated into land-use planning, may aid in ameliorating the adverse effects of inevitable urbanization and border security activities. If connectivity can be maintained, there is greater likelihood of the long-term persistence of species such as black bears, mountain lions, and jaguars along the US–Mexico border.

Acknowledgments

J. Ng, R. Butler, T. Smith, and S. Boe provided assistance with data collection. S. Stone, B. Wakeling, L. Ordway, M. Disney, R. Thompson, M. Crabb, and J. Hanna helped coordinate collection of additional bear samples. We thank the Commandant of Fort Huachuca for providing access to the base. ABSTRACT Cougar (*Puma concolor*) populations are a challenge to estimate because of low densities and the difficulty marking and monitoring individuals. As a result, their management is often based on imperfect data. Current strategies rely on a source–sink concept, which tends to result in spatially clumped harvest within management zones that are typically approximately 10,000 km². Agencies often implement quotas within these zones and designate management objectives to reduce or maintain cougar populations. We propose an approach for cougar management founded on their behavior and social organization, designed to maintain an older age structure that should promote population stability. To achieve these objectives, hunter harvest would be administered within zones approximately 1,000 km² in size to distribute harvest more evenly across the landscape. We also propose replacing the term “quota” with “harvest threshold” because quotas often connote a harvest target or goal rather than a threshold not to exceed. In Washington, USA, where the source–sink concept is implemented, research shows that high harvest rates may not accomplish the intended population reduction objectives due to immigration, resulting in an altered population age structure and social organization. We recommend a harvest strategy based on a population growth rate of 14% and a resident adult density of 1.7 cougars/100 km² that represent probable average values for western populations of cougars. Our proposal offers managers an opportunity to preserve behavioral and demographic attributes of cougar populations, provide recreational harvest, and accomplish a variety of management objectives. We believe this science-based approach to cougar management is easy to implement, incurs few if any added costs, satisfies agency and stakeholder interests, assures professional credibility, and may be applied throughout their range in western North America. © 2013 The Wildlife Society.

KEY WORDS cougar, harvest management, harvest quota, intrinsic growth rate, management zone, *Puma concolor*, regulation, social structure, source–sink, Washington.

The history of cougar (*Puma concolor*) management in Washington and for the western United States as a whole has been dominated by political and special interest agendas creating a challenge for wildlife managers (Kertson 2005, Beausoleil and Martorello 2008, Mattson and Clark 2010, Jenks 2011, Peek et al. 2012). This is magnified by the lack of reliable information on cougar population size, density, and outcomes of management strategies (Cougar Management Guidelines Working Group 2005). In recent decades, satellite and Global Positioning System telemetry and long-term field investigations in 6 different areas in Washington (Lambert et al. 2006; Robinson et al. 2008; Cooley et al. 2008, 2009a, b; Maletzke 2010; Kertson et al. 2011a, b; R. A. Beausoleil, unpublished data), and throughout the West (Logan and Sweanor 2001, Cougar Management Guidelines Working Group 2005, Stoner et al.

2006, Hornocker and Negri 2010, Robinson and DeSimone 2011) have elucidated cougar ecology, providing managers a new scientific basis to help guide management.

Behavior and social organization are important aspects of many species' biology and should be considered for management, particularly for low-density territorial carnivores occupying the apex of the trophic hierarchy (Wielgus and Bunnell 1994, Caro et al. 2009, Packer et al. 2009, Treves 2009, Estes et al. 2011). Maintaining mature cougars is important because they influence rates of immigration and emigration, spatial distribution, reproduction, and kitten survival (Cougar Management Guidelines Working Group 2005, Hornocker and Negri 2010; Cooley et al. 2009a, b).

We propose a science-based approach to regulated harvest management founded on cougar behavior and social organization, in which harvest is regulated to maintain an older age structure to promote population and social stability. This model for cougar management addresses concerns of various constituencies to 1) provide a sustainable harvest, 2) provide quality recreational experience to the hunting public, 3) maintain viable cougar populations, and 4) more explicitly

recognize the values of the non-consumptive public by maintaining the behavioral integrity of cougar populations.

We base our recommendations on research from Washington demonstrating that a high harvest rate may not accomplish local population reductions and may result in altering the age structure and social organization of the population. This may have unplanned consequences for cougar-prey dynamics and cougar-human conflict (Knopff et al. 2010, White et al. 2011, Kertson et al. 2013). More than US\$ 5 million and >13 years (1998–2011) have been invested in cougar research in Washington at 6 study sites across a diverse landscape (Fig. 1). We distill findings from these investigations and propose strategies to help managers navigate the myriad of agendas that encompass carnivore management for a more predictable management outcome, especially in the unpredictable atmosphere of politics and advocacy. Our objective for this review is to provide a data-driven management system that can be applied consistently among management units that incorporates both species behavior and human interests.

CURRENT COUGAR MANAGEMENT STRATEGIES

Management agencies throughout the west use a variety of strategies and techniques to regulate cougar harvest, including general-season hunts with no harvest limit or season restrictions, limiting the number of hunters through permits, and limiting harvest through quotas or bag limits. The use of trailing hounds to hunt cougars is permitted in the majority of states and provinces (Beausoleil et al. 2008). In this manuscript, we propose replacing the term “quota” with

“harvest threshold” because quotas often connote a harvest target or goal rather than a threshold not to exceed, and we propose that harvest should not exceed the intrinsic rate of population growth.

Current management strategies rely on a source-sink concept (Laundré and Clark 2003) and are administered within cougar management zones (CMZs), that are typically about 10,000 km² and often have management objectives to reduce or maintain cougar populations (Logan and Sweanor 2001). However, dispersal by cougars from adjacent areas may thwart efforts to locally reduce cougar populations (Lambert et al. 2006, Robinson et al. 2008; Cooley et al. 2009a). Conversely, where managers want to maintain cougar populations and apply harvest thresholds to zones, harvest may still be locally excessive when CMZs are >1,000 km² and the majority of the harvest occurs in clusters where hunter accessibility is relatively great (Ross et al. 1996). Although local population sinks may be re-populated by immigration of subadults, disruption may occur to the intrinsic social and spatial organization of the population, which may result in a demographic composition dominated by subadults (Lambert et al. 2006; Robinson et al. 2008; Cooley et al. 2009b). This situation may create unanticipated consequences, including an increase in the use of residential areas by cougars and in human-cougar complaints (Maletzke 2010, Kertson et al. 2011b).

HISTORY OF COUGAR MANAGEMENT IN WASHINGTON

Cougar management in Washington began in 1966 when their status changed from a bounty animal to a big-game species with hunting seasons and harvest limits (Washington

Figure 1. Six cougar research areas in Washington, USA, 2001–2012: (1) western WA; (2) central WA; (3) north-central WA; (4 and 5) northeast WA; (6) southeast WA.

Department of Fish and Wildlife [WDFW] 2008). This change came with a series of regulations, including mandatory reporting (1970), inspection and sealing of cougar pelts for demographic data (1979), and submitting a tooth from harvested animals for age analysis (mid-1980s). From 1980 to 1995, cougar harvest seasons remained static with a 6–8-week season.

Politics began to direct cougar management in 1996 when Washington voters approved Initiative 655 (I-655). Initiative 655 banned the use of dogs for hunting cougar and has been pivotal in framing the debate over cougar management in Washington since then (Kertson 2005, Beausoleil and Martorello 2008). With the use of dogs banned and anticipated decrease in cougar harvest, WDFW 1) replaced limited permit-only seasons with general seasons, 2) increased season length from 7.5 weeks to 7.5 months, 3) increased bag limits from 1 to 2 cougar/year, and 4) decreased the price of transport tags from US\$ 24 to \$ 5. The response to these changes resulted in increased tag sales from an annual average of 1,000 prior to I-655 to approximately 59,000/year since 1996, and this action increased harvest from an average of 121 (SD = 54, 1980–1995) to an average of 160 (SD = 44, 1996–2011)/year. Hunting opportunities and harvest were not evenly distributed, primarily increasing in areas where social tolerance for cougars was low, deer hunter density was high, and human access was high; during this time, cougar densities were unknown but assumed to be increasing (Jenks 2011, Lambert et al. 2006).

Since I-655 was approved, 16 legislative bills addressing cougar management have been introduced into the Washington legislature (<http://apps.leg.wa.gov/billinfo>). In 2000, Washington instituted a management concept to reduce cougar numbers in areas where complaints were high (Engrossed Substitute Senate Bill 5001-ESSB 5001). This bill and 3 others since 2003 (Substitute Senate Bill 6118-SSB 6118, Engrossed Substitute House Bill 2438-HB 2438, and Engrossed Substitute House Bill 1756-HB 1756) permitted the use of dogs in 6 counties, effectively overturning I-655 in many areas throughout Washington. In 2011, House Bill 1124 was introduced to continue hunting with hounds but failed to pass, and since the use of dogs has been prohibited statewide. However, ESSB 5001 allows the WDFW to authorize a hunt with the use of dogs when reports of conflicts with humans or their livestock exceed the previous 3-year running average.

In the midst of the political activity between 1996 and 2010, which included legislative mandates, WDFW began integrating insights from harvest monitoring (Martorello and Beausoleil 2003), and research projects (Robinson et al. 2008; Lambert et al. 2006; Cooley et al. 2009a, b; Kertson 2010; Maletzke 2010). In 2003, harvest thresholds in conjunction with a 24-hour hunter reporting hotline allowed for prompt closure of zones where the use of dogs was permitted. In 2009, the WDFW reduced the bag limit to 1 cougar/hunter/year, shortened season length to avoid some overlap with deer and elk seasons, and restricted harvest with female- and total-harvest thresholds. In 2011, WDFW managers and researchers compiled research findings and

began drafting a new management strategy, an aspect of which was publicly reviewed and ultimately adopted by the Washington Fish and Wildlife Commission in spring 2012. Here, we present a synthesis of this research and develop these concepts into a management strategy.

COUGAR ABUNDANCE AND DENSITY: BEHAVIORAL CONSIDERATIONS

Estimating cougar abundance and density, as with most species, represents one of the most challenging aspects of their management. Currently, reliable estimation of cougar abundance requires expensive, field-intensive, long-term research (Hornocker and Negri 2010). Consequently, agencies use numbers of cougar complaints, cougar–human conflicts, and harvest as proxies for population size and trend (Martorello et al. 2006). However, cougar complaint reports can be unreliable (Kertson et al. 2013), and it has been shown that increasing numbers of complaints and increasing predation on mule deer (*Odocoileus hemionus*), and endangered mountain caribou (*Rangifer tarandus caribou*) in a large (10,000-km²) heavily hunted CMZ in the Selkirk Mountains Ecosystem in northeastern Washington, northern Idaho, and southern British Columbia did not correspond to increasing densities of cougars (Katnik 2002, Robinson et al. 2002, Lambert et al. 2006). Thus, the indirect proxies of population size appeared to be plausible but were inaccurate in that heavily hunted CMZ that had approximately 38% annual removal rate of cougars.

Subsequent research in Washington was designed to examine the previous hypothesis (Lambert et al. 2006) of no direct positive correlation between harvest numbers and complaints and population densities of cougars. Working in the heavily hunted (24% of population harvested/yr), area of Kettle Falls in northern Washington, a declining female cougar population was documented as the male segment increased due to compensatory juvenile male immigration (Robinson et al. 2008). In another study area in central Washington, (Cle Elum), an opposite scenario was confirmed in that relatively low hunting mortality (11%/yr) resulted in a net emigration of younger males (Cooley et al. 2009a). In all cases, the population densities were remarkably similar, ranging from 1.5 to 1.7 adult (>2-yr-old), cougars/100 km² with total densities of about 3.5 cougars/100 km², including kittens and subadults. Details on estimating population densities and immigration–emigration rates have been described (Robinson et al. 2008; Cooley et al. 2009a, b; Robinson and DeSimone 2011). Additional research on 2 other study areas in western and north-central Washington showed an average resident adult density of about 1.6/100 km² and a total density of about 3.4/100 km² (R. A. Beausoleil and B. N. Kertson, unpublished data). In 3 separate study areas in Washington and Montana, increased hunting (11–38% population harvest rates) did not result in compensatory increases in cub production, cub survival, or adult survival (Robinson et al. 2008; Cooley et al. 2009a, b; Robinson and DeSimone 2011). However, variation in hunting mortality did result in compensatory immigration–emigration by primarily young males, with no net differences

in total cougar numbers. Such compensatory immigration has been observed in many other highly mobile species as well (Beecham and Rohlman 1994, Merrill et al. 2006, Turgeon and Kramer 2012, Mills 2013). Therefore, increased hunting may not always result in reduced local densities of cougars, but not due to traditional density-dependent effects such as compensatory reproduction and survival; instead, increased hunting may result in compensatory immigration by mainly young males (Cooley et al. 2009*b*).

Presenting and comparing density estimates between studies is challenging because standardization is lacking (Quigley and Hornocker 2010). For example, whereas total density could temporarily fluctuate in response to immigration and emigration of subadults, density of resident breeding adults tends toward stability over time. Density estimates can also be misinterpreted from incomplete data due to differences in seasonal spatial use patterns where individuals concentrate on low-elevation ungulate winter ranges, often comprising only a portion of the population's annual distribution (Maletzke 2010). When annual boundaries of individual cougar territories are unknown, density estimates may result in inflated values and substantial overestimation of population size (Maletzke 2010). However, there is remarkable consistency in the western United States and Canada where long-term research has been conducted; resident adult densities average 1.6 cougar/100 km², while total densities including kittens and subadults average 2.6 cougar/100 km² (Quigley and Hornocker 2010). Our research in Washington corroborates these findings because adult densities averaged 1.7/100 km² (Cooley et al. 2009*b*; R. A. Beausoleil and B. N. Kertson, unpublished data). Therefore we encourage a more explicit, standardized approach of using estimates of adult densities for population management objectives and caution against using total densities, because they do not provide for reliable estimation of population parameters and harvest impacts (Robinson et al. 2008; Cooley et al. 2009*b*).

In Washington, where prey biomass was consistent and cougar harvest ranged from 11% to 38% of the cougar population per year, the age structure, survival, sex ratio, reproductive rate, and spatial use patterns of cougars differed (Lambert et al. 2006; Cooley et al. 2009*b*; Maletzke 2010). Where annual harvest was 24%, mean age at harvest was 27 months compared with 38 months where annual harvest was 11%. In addition, in areas of greater relative harvest, male home-range sizes were larger (753 km² vs. 348 km²), and home-range overlap between males was greater (41% vs. 17%). Cougars, especially males, evolved with a social dynamic to patrol and defend a territory regardless of whether their home-range size is determined by prey density or social tolerance (Hornocker 1969, Pierce et al. 2000, Logan and Sweanor 2010). As adult mortality increases, territorial boundaries diminish. Immigrating subadults may establish home ranges readily, and their home ranges may overlap significantly, which may influence rates of predation and the distribution of prey and potentially increase probabilities for interactions with humans (K. A. Peebles, Washington State University, unpublished data).

The social system and territoriality observed for cougars is similar among many species of solitary felids, although it may manifest itself differently for males and females (Sunquist and Sunquist 2002). Although the role of social ecology for cougars will continue to be debated in the future, it is important to acknowledge that harvest intensity can affect spatial use patterns of cougars as well as their population demographics, as demonstrated for other hunted carnivore populations (Packer et al. 2009).

HARVEST MORTALITY VERSUS TOTAL MORTALITY

Although knowledge of population abundance and density is critical for sound management of cougars, it is also important that managers be aware that harvest mortality can be additive to natural mortality (Robinson et al. 2008; Cooley et al. 2009*b*; Robinson and DeSimone 2011). Failing to account for and include all mortality sources may obscure estimates of population trajectory and underestimate the impact of harvest on demographics and cougar social structure (Cooley et al. 2009*b*; Morrison 2010; Robinson and DeSimone 2011). Unfortunately, reliable knowledge of non-harvest mortality is difficult to quantify (Cougar Management Guidelines Working Group 2005), because harvest may not necessarily be representative of age structure of the population (R. A. Beausoleil, B. N. Kertson, and G. M. Koehler, unpublished data).

To illustrate the importance of considering non-harvest mortality, we documented 79 mortalities of radiomarked cougars during 4 concurrent research efforts in Washington. Of these, 49% were non-hunter harvest mortalities; 14% from agency control, 6% from intraspecific strife, 6% due to motor-vehicle collisions, 4% from disease, 4% attributed to Native American predator-control efforts, 3% due to injuries sustained during pursuit of prey, 3% from poaching or illegal harvest, and 10% from undetermined sources. In the western Washington study area, hunter harvest mortality averaged ≤ 2 animals/year from 2003 to 2008 and annual survival rate of the study population was 55% (SD = 7.8, $n = 5$ yr; B. N. Kertson, unpublished data). A significant mortality factor for this population was from feline leukemia virus exposure along the wildland-urban interface, resulting in an observed average annual survival rate of 55%, less than that for a heavily hunted population in Washington with 79% annual survivorship (Cooley et al. 2009*b*). These examples demonstrate the importance that non-harvest mortality can have in cougar population dynamics.

POPULATION GROWTH AND MAXIMUM SUSTAINED YIELD

The growth rate for an unhunted population, or intrinsic rate of population growth, can be described as the rate we expect the population to grow if it did not experience additive hunting mortality. Because kitten mortality and non-harvest mortality can be additive to hunting mortality, we calculated the intrinsic growth rate by censoring all harvest mortalities. In Washington, the unhunted growth rate was 1.14 (SD = ± 0.023) for 3 different populations (Selkirk Moun-

tains, Kettle Falls, and Cle Elum; Morrison 2010). The intrinsic growth rate in northwest Montana was estimated by removing hunting that resulted in a population growth rate of 1.15–1.17 (Robinson and DeSimone 2011). Although growth rate may be considered equivalent to the maximum sustainable yield, the rate of growth for an unhunted population should not be the goal for harvest but rather a maximum not to exceed if a stable population is to be achieved. Using maximum sustainable yield as a management target has been cautioned against, because it does not incorporate the uncertainty of stochastic events on population abundance and may present a potential for over-harvest (Caughley and Sinclair 1994). Setting adult harvest limits to the intrinsic rate of growth of 14% should help to balance immigration and emigration among harvest units and result in greater stability of cougar densities and age structure.

HARVEST UNITS AND HARVEST THRESHOLDS

Cougars are often managed in administrative zones (Logan and Sweanor 2001), which represent an amalgam of smaller Game Management Units (GMUs). Commonly these CMZs are designated as population “sources” and “sinks” where management objectives are to maintain or decrease population levels, respectively (Laundré and Clark 2003). In Washington, 139 GMUs are partitioned throughout the state and are used to manage harvest and habitat for a variety of game species (Fig. 2). In 2011, these GMUs were combined into 13 CMZs, each comprised from 3 to 22 GMUs and encompassing 1,873–14,947 km² of forested and

shrub-steppe habitat (total = 90,783 km²; Fig. 3). Five CMZs had a harvest limit of 6–20 cougars, and 8 did not have limits. Individual GMUs with high hunter access and suitable snow conditions accounted for 25–50% of the total harvest within the CMZs, which has been repeated over multiple years (WDFW 2011). This uneven distribution of harvest, or harvest clustering, may create local population sinks in areas within CMZs designated as sources and may disrupt the social organization of cougars as previously explained. Additionally, this uneven distribution of harvest may result in some GMUs with little or no harvest, creating angst among hunters who feel harvest opportunity was inequitable.

Setting harvest thresholds can help to distribute harvest, minimize risk of overharvest (Ross et al. 1996), and help maintain recreational opportunity and quality of hunter experience. However, it is important to note that harvest thresholds may become less effective for distributing harvest as CMZ size increases, and harvest may be concentrated within areas where access is high (i.e., harvest clustering). Harvest thresholds to limit harvest may be more effective where harvest is distributed evenly among GMUs rather than applied to the larger CMZs. Where GMUs are small, habitat is limited, or a quota of ≤ 1 cougar is allocated, combining adjacent GMUs to reach a size of approximately 1,000 km² may be recommended.

HUNTER CONSIDERATIONS

Age and sex of harvest can be an important factor influencing population dynamics of big-game species. Unlike ungulates

Figure 2. Distribution of cougar habitat (shaded dark) and current game-management units (outlined in black) in Washington, USA, Washington Department of Fish and Wildlife, 2012.

Figure 3. 2011 cougar management zones in Washington, USA, Washington Department of Fish and Wildlife, 2012.

for which juvenile status and sex are readily identifiable, most hunters are unable to distinguish female cougars from males and adults from subadults until after the animal is killed. Where the use of dogs is permitted, sex, and age determination may be more reliable but not certain due to restricted visibility of treed animals.

Many agencies employ a general open season and a permit-only season for cougar. Two concerns for hunters who participate in permit-only hunts (either limited-entry or quota hunts) are 1) when harvest threshold tallies begin during a general open season (which often overlaps with deer and elk season), and that, when filled, nullify the permit-only season; and 2) when the number of permits issued is greater than harvest threshold, thus creating a competitive atmosphere (the use it or lose it conundrum). In Washington, for example, 10–35 permits were issued for CMZs with harvest objectives for 6–20 cougars.

IMPLEMENTATION

The first step for applying our proposed management framework is to estimate the amount of cougar habitat. For Washington, we plotted 85,866 Global Positioning System and satellite telemetry locations from 117 radiocollared cougars in 5 study areas into U.S. Fish and Wildlife Service–U.S. Geological Survey Landfire habitat coverage (LANDFIRE 2007) using ArcMap 9.3. We quantified the number of Global Positioning System locations in each habitat type, created a Geographic Information System data layer identifying habitats used by marked cougars, and extrapolated these habitats throughout the state. The result included 90,783 km² of the 104,000 km² of habitat for areas where

WDFW has management authority (Fig. 1). For states and provinces lacking empirical estimation of suitable habitat for cougars, reliable and quantifiable estimates of forest cover, topographic variability, limited residential development (not to exceed exurban densities), and persistent ungulate prey may provide reasonable measure of suitable habitat for cougars (Burdett et al. 2010; Maletzke 2010; Kertson et al. 2011b). However, where existing Geographic Information System coverages may not reflect current landscape conditions, we advocate they be ground-truthed to avoid overestimating habitat. Including district or regional biologists and officers can also be advantageous.

We then overlaid current GMU boundaries onto this habitat coverage to calculate the available habitat within each GMU, and we applied adult densities of 1.7 cougars/100 km² to estimate the number of adult residents per GMU. Where GMUs were small (<750 km²), or the habitat sparse, we combined adjacent GMUs; this resulted in 62 CMZs for Washington (Fig. 4). In jurisdictions where densities are not estimable, we suggest that the scientifically defensible average of 1.6 adults/100 km² be applied (Quigley and Hornocker 2010).

We applied a mean intrinsic rate of growth of 14% (Morrison 2010) to allocate harvest of adult cougar per unit of area (0.24 cougars/100 km² of habitat). For Washington, this resulted in a statewide annual harvest of 220 cougars, more than the average annual harvest from previous years. Although the proposed harvest would be greater, this harvest would be distributed more evenly across management units in the state, resulting in a more uniformly distributed hunter effort, less harvest clustering and population sinks, and

Figure 4. Proposed cougar management zones for Washington, USA, 2012.

greater stability in the cougar population. This strategy may prevent the need for harvest thresholds based on sex and could simplify harvest regulations and administration. We recommend using the harvest threshold of 14%. In addition, because subadult age classes are dynamic and difficult to estimate, and difficult to identify in the field, we recommend that harvest of this age class be counted against the allocated harvest so that recruitment is not affected in the future. Finally, we advocate administering the hunt using a 24-hour reporting and information hotline because it allows for prompt reporting of kills and CMZ closure and provides hunters the opportunity to plan hunt activity.

Administering harvest thresholds for GMUs or smaller CMZs has multiple benefits. It helps to 1) preserve the cougar's social organization by distributing harvest more evenly and avoiding creation of population sinks, 2) eliminate the need for harvest thresholds based on sex and for field identification of sex, 3) distribute hunter opportunity across the landscape, and 4) define a biological and meaningful spatial scale similar to that of their prey (ungulates), bringing management for predator and prey into alignment.

MANAGEMENT IMPLICATIONS

We acknowledge that these recommendations are based on research in Washington, but similar findings have been documented elsewhere in western North America (Quigley and Hornocker 2010). For the most part, current cougar management programs do not address the effects of harvest on social structure of cougar populations, a concept that was introduced >40 years ago (Hornocker 1969, 1970) and is supported by current research. We believe this science-based

approach to cougar management is easy to implement, incurs no added costs, satisfies agency and stakeholder interests, and assures professional credibility. The current review of carnivore management has demonstrated a paradigm shift from lethal control to one of ecosystem management, and one that considers the values of multiple stakeholders and aspects of human dimensions (Treves 2009, Hornocker and Negri 2010, Van Ballenberghe 2011, Way and Bruskotter 2012, Peek et al. 2012). Our recommendations incorporating cougar behavior and social organization into a management framework addresses concerns of various constituencies, provides for quality hunter experience, and recognizes values of the non-consumptive public while maintaining viable cougar populations and the behavioral integrity of their populations.

A simple, consistent, science-based approach to cougar management can be of benefit to agencies during intervals of administrative and political uncertainty. In addition to fulfilling agency mandates for hunter opportunity, our proposal adheres to our state agency's mission to "promote development and responsible use of sound, objective science to inform decision making" (WDFW 2008). In our opinion, of equal importance is recognizing the ecological and evolutionary role of cougar in the trophic hierarchy (Estes et al. 2011); and incorporating this concept into management and education elevates the cougar's status beyond a mere predator.

ACKNOWLEDGMENTS

We thank M. G. Hornocker, H. S. Robinson, and H. S. Cooley for comments that helped improve the initial

manuscript. S. Haskell, K. Knopff, and an anonymous reviewer provided a constructive critique. We would also like to thank the highly experienced hound handlers involved in making our projects successful; they include D. Clark, R. Culver, K. Lester, D. Likens, S. Reynaud, R. Schultz, B. Smith, C. Smith, and M. White.

Research Article

Variation in Life History and Demography of the American Black Bear

JULIE A. BESTON,^{1,2} *Wildlife Biology, University of Montana, Missoula, MT 59812, USA*

ABSTRACT Variation in life history and demography across a species' range informs researchers about regional adaptations and affects whether managers can borrow information from other populations in decision-making. The American black bear (*Ursus americanus*) is a long-lived game species whose continued persistence depends on management of harvest and removal of habituated bears that come into conflict with humans. Understanding the demography of black bears guides efforts at management and conservation, yet detailed knowledge of many populations is typically lacking. I performed a hierarchical Bayesian meta-analysis of black bear demographic studies across the geographic range of the species to explore how vital rates vary across the range, what information they give us about population growth, and whether managers can justify borrowing information from other studies to inform management decisions. Cub, yearling, and adult survival and fecundity varied between eastern and western North America, whereas subadult survival did not show geographic structuring. Adult survival and fecundity appeared to trade off, with higher survival in the western portions of bears' range and higher fecundity in the east. Although adult survival had the highest elasticity, differences in reproduction drove differences in population growth rate. Mean population growth rate was higher in the east (0.99; 95% credible interval [CrI]: 0.96, 1.03) than the west (0.97; 95%CrI: 0.93, 1.01). Despite declining trends in the west, 34% of the distribution of population growth rate was >1, compared to 55% in the east. Further work needs to be done to address the cause of the apparent trade-off between adult survival and fecundity and explore how the estimated growth rates are likely to affect population status of black bears. Because population growth rates are close to 1 and small deviations could impact whether a population is considered increasing or decreasing, managers need to employ caution in borrowing vital rates from other populations. © 2011 The Wildlife Society.

KEY WORDS Bayesian meta-analysis, black bear, demography, life history, populations, *Ursus americanus*.

Conservation and management decisions often rely on information about a species' life history and demographic rates, and variation in these traits informs us about pressures populations face and potential impacts of management decisions. Variation in life history among populations of a particular species has been demonstrated in a variety of taxa, from fish (Johnson and Zuniga-Vega 2009) to deer (Nilsen et al. 2009). These differences affect population growth, persistence, and responses to management (Brown 1985, Dobson and Murie 1987, Nilsen et al. 2009). Just as species that reproduce quickly recover more easily from disturbance and exploitation than long-lived species with slower reproduction, so too, populations within a species may differ in their response to management due to faster or slower life histories. These differences also affect whether we can generalize studies of individual populations to reduce costs of new studies and target gaps in the current knowledge base.

Many large carnivores have wide distributions in varied environments that may induce variation in life history. They are also frequently targets of harvest, control, or conservation actions whose cost and effectiveness vary with life history and demography of individual populations. For example, brown bears (*Ursus arctos*) are more productive in their coastal North American range than in continental areas due to availability of spawning salmon (Hilderbrand et al. 1999). Coastal populations may sustain a higher harvest rate than inland populations due to greater reproduction. Likewise, the effect of extra wild dog (*Lycaon pictus*) helpers on reproduction varies spatially with ecological conditions, and this affects the appropriate pack size for an enclosed reserve (Gusset and Macdonald 2010).

Management can also induce important spatial variation. Cougars (*Puma concolor*) show strong source-sink dynamics when heavily harvested areas are adjacent to undisturbed populations (Robinson et al. 2008, Cooley et al. 2009). Efforts at reduction of cougars in target areas were fruitless unless survival was suppressed over a wide area (Cooley et al. 2009). Similarly, sanctuaries appear to provide some refuge for harvested black bear (*U. americanus*) populations in the southeast United States (Powell et al. 1996), and maintaining unhunted areas may bolster hunted populations on neighboring lands. Spatiotemporal variation in historic

overexploitation has also induced life history variation among sea otter (*Enhydra lutris*) populations in the North Pacific (Monson et al. 2000). Populations that have not fully recovered exhibit higher weaning success than those that have reached carrying capacity (Monson et al. 2000). It is clear that spatial variation in vital rates and life history through natural variations or anthropogenic differences should affect management decisions. However, there have been few attempts to describe geographic structure in life history across the range of a large carnivore.

Black bears are widely distributed in a variety of ecosystems in North America, which could lead to variation in life history. Black bears rely heavily on seasonally available hard and soft mast as well as prey, and variation in food has been shown to correlate with differences in reproduction and survival of young (Schwartz and Franzmann 1991). Because they depend on primary productivity that varies among the biomes they inhabit, life history and vital rates of black bears may also vary among populations in different biomes. Variation in harvest pressure could also affect life history by depressing adult survival (Czetwertynski et al. 2007, Obbard and Howe 2008), which generally has a strong impact on population growth of long-lived species (Heppell et al. 2000, Sæther and Bakke 2000). At a broad scale, black bears in eastern North America were isolated from those in western North America during the Pleistocene (Wooding and Ward 1997), and there is a long-standing perception that populations in the 2 halves differ in population dynamics. Researchers sometimes refer to the vital rates of “eastern” or “western” black bears in papers without explaining why such a distinction has been made (e.g., Rossell and Litvaitis 1994, Garrison et al. 2007, Baldwin and Bender 2009). Others have observed contrasts between estimates of vital rates, especially reproduction, from the 2 halves of their range (Kasworm and Thier 1994), but to my knowledge there has been no systematic examination of how their life history varies across their range.

Regional differences in life history may determine the efficacy of management and conservation strategies for this charismatic carnivore. Black bears are hunted throughout much of their range and can become pests near agricultural and urban food sources (Lariviere 2001, Hristienko and McDonald 2007). Managers are faced with the challenge of ensuring persistence while allowing for harvest and nuisance removals. Demographic differences can affect what management strategies are acceptable. Hristienko and McDonald (2007) suggest that western and northern populations should be managed more conservatively because food is less abundant, presumably resulting in lower reproductive output. Alternatively, little variation in life history may mean information can easily be generalized to help guide management across the range.

Many demographic studies have been conducted on black bears, and this information may provide useful insights for managers and researchers. I synthesized work on black bear demography in a Bayesian meta-analysis to assess how their life history varies across space and whether managers can borrow information from other populations in making man-

agement decisions. I constructed a simple matrix population model to estimate population growth rate, compared population growth across their range, and evaluated realized consequences of differences in vital rates (Wisdom et al. 2000). I explored whether the general pattern of high adult survival with high elasticity found in several studies of individual bear populations (Eberhardt 1990, Wielgus et al. 2001, Freedman et al. 2003) holds throughout the range of black bears. I also used model selection to test whether geographic structure is apparent among vegetation and climatic communities using ecoregions (Bailey 1998) and between eastern and western North America.

METHODS

I conducted a literature search for black bear demography and used a citation search to identify further studies. I searched Web of Science (Thomson Reuters, apps.isiknowledge.com, accessed 2008–2010) and Google Scholar (Google, scholar.google.com, accessed 2008–2010) for “black bear and demography or life history or vital rate or survival or reproduction.” I sent information requests to every state and provincial agency mandated to manage black bears. I also included vital rates reported in papers or tables by third party authors where I could not acquire the original source. I recorded cub, yearling, subadult and adult survival, fecundity, age at primiparity, litter size, interbirth interval, sample sizes, and standard errors, as well as location, time period, and whether the population was harvested. If 2 studies were based on the same data, I excluded the older study because the newer study usually either added data or improved the analysis. I also excluded estimates of vital rates when they relied on covariates other than region, such as food supply (e.g., Obbard and Howe 2008, adult survival), and were therefore not comparable with estimates from other studies. Bears are polygamous, and females drive population growth because a single male can impregnate several females (Lariviere 2001). Therefore, when different survival rates were reported for each sex, I used only information from female bears.

To combine estimates of vital rates from different studies in the meta-analysis, I used measures of precision to incorporate differing levels of uncertainty. I used the squared standard error to produce a measure of uncertainty associated with each vital rate estimate. When standard error of survival (s) was not reported, I calculated it using the sample size (n ; Sokal and Rohlf 1995):

$$SE(s) = \sqrt{\frac{s(1-s)}{n}}$$

When fecundity (f) or its standard error were not reported, I used $f = 1/(2 \times b)$ to calculate fecundity, where l is litter size and b is interbirth interval. This assumes a 1:1 sex ratio at birth. I then found the standard error by propagating the errors of litter size and interbirth interval:

$$SE(f) = \sqrt{\left(\frac{\partial f}{\partial l} SE(l)\right)^2 + \left(\frac{\partial f}{\partial b} SE(b)\right)^2}$$

If I could not employ these methods, usually because sample size was missing, I set the standard error equal to the greatest standard error recorded for the other estimates of that vital rate. I used the squared standard error to weight studies in the meta-analysis by adding it to the variance at the lowest level of the hierarchy. Studies with more precise estimates of vital rates therefore had greater weight in the model fitting and studies with large or unknown standard error had least weight.

I modeled age at primiparity with a stretched and translated beta distribution, which is flexible and has upper and lower bounds that can be manipulated to suit the data. The youngest observed mean primiparity was 3 and the oldest was 8, so I set the limits at 2.5 and 8.5. To estimate the distribution, I converted the estimates to a standard beta scale, which is bounded by 0 and 1, by subtracting the lower limit, 2.5, and dividing by the range, 6. I assumed the probability of the mean age at primiparity being i was equal to the probability under the estimated stretched beta from $i - 0.5$ to $i + 0.5$.

I combined estimates of survival, fecundity, and age at primiparity using a set of 6 hierarchical models to identify the appropriate geographic structure for each vital rate (Tables 1 and 2). I considered combinations of 3 intermediate geographic levels between the study level and the entire range: ecoregion provinces and ecoregion divisions (Bailey 1998), and eastern and western halves of the continent. Ecoregions group areas with similar climate and vegetative communities, and each division is comprised

Table 1. Suite of models^a used to estimate cub, yearling, subadult, and adult survival, fecundity, and age at primiparity in a meta-analysis of black bear demographic studies from across North America, 1959–2007.

Model	Survival and primiparity ^b	Fecundity ^b
Non-hierarchical	$s_i \sim \beta[A(\mu_i, \sigma_i^2), B(\mu_i, \sigma_i^2)]$ $\sigma_i^2 = \sigma^2 + SE_i^2$	$s_i \sim LN(\mu_i, \sigma_i^2)$ $\sigma_i^2 = \sigma^2 + SE_i^2$
Halves or divisions or provinces	$s_{ij} \sim \beta[A(\mu_j, \sigma_{ij}^2), B(\mu_j, \sigma_{ij}^2)]$ $\sigma_{ij}^2 = \sigma_j^2 + SE_{ij}^2$ $\mu_j \sim \beta(a, b)$ $\mu = \frac{a}{a+b}$ $\sigma^2 = \frac{a \times b}{(a+b)^2(a+b+1)}$	$s_{ij} \sim LN(\mu_j, \sigma_{ij}^2)$ $\sigma_{ij}^2 = \sigma_j^2 + SE_{ij}^2$ $\mu_j \sim N(\mu, \sigma^2)$
Divisions—halves or provinces—halves	$s_{ijm} \sim \beta[A(\mu_{jm}, \sigma_{ijm}^2), B(\mu_{jm}, \sigma_{ijm}^2)]$ $\sigma_{ijm}^2 = \sigma_{jm}^2 + SE_{ijm}^2$ $\mu_{jm} \sim \beta[A(\mu_m, \sigma_m^2), B(\mu_m, \sigma_m^2)]$ $\mu_m \sim \beta(a, b)$ $\mu = \frac{a}{a+b}$ $\sigma^2 = \frac{a \times b}{(a+b)^2(a+b+1)}$	$s_{ijm} \sim LN(\mu_{jm}, \sigma_{ijm}^2)$ $\sigma_{ijm}^2 = \sigma_{jm}^2 + SE_{ijm}^2$ $\mu_{jm} \sim N(\mu_m, \sigma_m^2)$ $\mu_m \sim N(\mu, \sigma^2)$

^a Where β , N , and LN refer to the beta, normal, and lognormal distributions, respectively, and $A(x, y) = x\{[(x-x^2)/y]-1\}$, $B(x, y) = (1-x)\{[(x-x^2)/y]-1\}$ are the shape parameters of the beta distribution with mean x and variance y .

^b See Table 2 for variable definitions

Table 2. Parameter definitions for hierarchical models of black bear vital rates from North America, 1959–2007.

Variable	Meaning
s_i	Vital rate estimate for the i th study
s_{ij}	Vital rate estimate for the i th study in the j th province, division, or half
s_{ijm}	Vital rate estimate for the i th study in the j th province or division in the m th half
μ_j	Mean vital rate value for the j th province, division, or half
μ_{jm}	Mean vital rate value for the j th province or division in the m th half
μ_m	Mean vital rate value for the m th half
μ	Overall mean vital rate value
σ_i^2	Variance among studies
σ_{ij}^2	Variance among study estimates within the j th province, division, or half
σ_j^2	Variance among populations within the j th province, division, or half
σ_{ijm}^2	Variance among study estimates within the j th province or division in the m th half
σ_{jm}^2	Variance among populations within the j th province or division in the m th half
σ_m^2	Variance among provinces or divisions within the m th half
σ^2	Variance among studies, provinces, divisions, or halves
SE_i	Standard error estimate for the i th study
SE_{ij}	Standard error estimate for the i th study in the j th province, division, or half
SE_{ijm}	Standard error estimate for the i th study in the j th province or division in the m th half

of 1–4 provinces. For example, most of the southeastern United States is in the Subtropical Division, which contains 3 provinces: Mississippi riverine forests in the western part of the division, southeastern mixed forests in the center, and coastal plain forests in the east. There was a natural break in study locations, with none occurring between -95° and -105° longitude (Fig. 1), roughly corresponding to the Great Plains, which served as the divider between east and west. I made an exception for Obbard and Howe (2008) because the ecoregion it was in stretches across Canada and into Alaska, the other studies in the ecoregion were in the west, and the climate and human population density more closely resemble the west than the east. The null model included no hierarchy. Three models incorporated a single level hierarchy; the studies were grouped by province, division, or half. Two further models had 2 levels, either province and half or division and half. I also included a set of models that incorporated harvest as an indicator variable, but these did not perform well, probably because harvest management varies widely among studies and thus harvest does not have a consistent effect across populations.

I fit models using package R2WinBUGS to call WinBUGS (WinBUGS Version 1.4.3, www.mrc-bsu.cam.ac.uk/bugs/winbugs, accessed 13 Jan 2009) from R (R Version 2.8.1, www.r-project.org, accessed 13 Jan 2009). I monitored convergence with the potential scale reduction factor, \hat{R} (Gelman et al. 2004, Sturtz et al. 2005). I compared models using the deviance information criterion (DIC) calculated with pV (Gelman et al. 2004). I conducted subsequent analyses using the best supported model for each vital rate.

Figure 1. Locations of black bear demographic studies across North America, 1959–2007, reporting at least one vital rate; cub, yearling, subadult, or adult survival, reproduction, or age at primiparity; included in the hierarchical Bayesian meta-analysis.

I used the vital rates from the meta-analysis to parameterize a density-independent post-birth pulse matrix model (Caswell 2001):

$$\begin{bmatrix} 0 & 0 & m_{2f} & m_{3f} & \cdots & m_{8f} & m_{9f} \\ s_0 & 0 & 0 & 0 & \cdots & 0 & 0 \\ 0 & s_1 & 0 & 0 & \cdots & 0 & 0 \\ 0 & 0 & s_2 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & 0 & 0 \\ 0 & 0 & 0 & 0 & \cdots & s_8 & s_9 \end{bmatrix}$$

where

$$s_i = \begin{cases} s_c & \text{for } i = 0 \\ s_y & \text{for } i = 1 \\ s_s & \text{for } i = 2 \\ s_s(1-p_i) + s_a p_i & \text{for } i = 3, \dots, 8 \\ s_a & \text{for } i = 9 \end{cases}$$

is the survival of bears from age i to age $i + 1$ given stage specific survival of cubs (c), yearlings (y), subadults (s), and adults (a),

$$m_i = \begin{cases} s_s p_{i+1} & \text{for } i = 2 \\ s_s(p_{i+1} - p_i) s_a p_i & \text{for } i = 3, \dots, 8 \\ s_a & \text{for } i = 9 \end{cases}$$

is the proportion of i aged bears that will survive and be mature at age $i + 1$, f is fecundity (number of female cubs per female per year), and p_i is the probability that the mean age at primiparity is i or younger. I assumed the age at which bears reach sexual maturity is constant within a given region, but unknown. I also performed analyses using an age-structured matrix in which all bears had the same age at primiparity, set to the mean of the region rounded to the nearest integer, and had a maximum age of 25 years (Hebblewhite et al. 2003).

This analysis led to essentially identical conclusions, so I do not discuss it here.

I used the matrix model to calculate the asymptotic population growth rate (λ) and the sensitivities and elasticities of the survival and fecundity vital rates (Caswell 2001). I bootstrapped survival and fecundity using their standard errors and variances among studies to find the posterior distributions of mean population growth rate and individual population growth rates, respectively. Whereas sensitivity describes the change in lambda with an incremental change in the vital rate, elasticity describes the change in lambda with a proportional change in a vital rate (Caswell 2001). However, because the effects of vital rates on lambda also depend on the amount of variation in each vital rate (Wisdom et al. 2000), I also compared the pattern of variation in vital rates among areas with estimated population growth rates.

RESULTS

I collected data on 86 black bear populations from 76 studies (see Table S1, available online at www.onlinelibrary.wiley.com). Fifty-nine populations were in eastern North America and 27 were classified as western (see Table S2, available online at www.onlinelibrary.wiley.com). Studies spanned the geographic range of black bears (Fig. 1). The final dataset included 55 estimates of cub survival, 23 estimates of yearling survival, 23 estimates of subadult survival, 52 estimates of adult survival, 32 estimates of fecundity, and 35 estimates of age at primiparity.

Most vital rates appeared to vary most between the east and west halves of the continent (Table 3). For fecundity, yearling and adult survival, and age at primiparity, the best model was structured by eastern and western North America. The best supported model for cub survival included division structuring. The highest cub survival values (0.64–0.72) were found in more northerly divisions, and the lowest value

Table 3. Differences in deviance information criterion (Δ DIC) for hierarchical geographic models of black bear vital rates across North America, 1959–2007.

Model	Cub survival	Yearling survival	Subadult survival	Adult survival	Fecundity	Age at primiparity
Null	12.84	0.51 ^b	0.00 ^a	0.10 ^b	12.12	7.64

^a Best model for each vital rate.^b Models with substantial support for each vital rate.**Figure 2.** Mean black bear cub survival values across North America estimated for each ecosystem division in the hierarchical Bayesian meta-analysis based on demographic studies spanning 1959 to 2007.

(0.54) was, not surprisingly, from the desert southwest (Fig. 2). To estimate population growth rates, I chose to use the halves model for cub survival, which was also well supported (Δ DIC = 1.455). This model allows for more direct comparisons and maintains comparable levels of variation in the different vital rates. Researchers or managers interested in a specific ecosystem division can use the cub survival estimates from that particular area as a starting point or informative prior. Subadult survival data showed some support for the halves model (Δ DIC = 2.357), but the posterior distributions of the eastern and western means in the halves model overlapped greatly with one another. I therefore chose to use the nonhierarchical model for subadult survival rate, which was the best supported model.

In the east, average adult female survival was 0.82 (95% credible interval [CrI]: 0.77, 0.86) and fecundity was 0.58 (0.54, 0.62). In the west, adult survival was higher than in the east (0.88; 95%CrI: 0.83, 0.92), but fecundity was lower

(0.46; 95%CrI: 0.36, 0.54). Mean age at primiparity in the east (4.46; 95%CrI: 4.02, 4.96) was also lower than that in the west (5.58; 95%CrI: 5.06, 6.07). There was an apparent negative relationship between adult survival and fecundity (Table 4). The pattern was also evident in the sensitivities and elasticities, with the sensitivity and elasticity of adult survival higher in the west than east and that of fecundity higher in the east than west (Table 5).

Analysis of the mean population growth rate (λ) for each half showed that population growth was positively correlated with both survival and fecundity (matrices, Fig. 3; correlations, Fig. 4). Eastern populations tended to have higher population growth despite their generally lower adult survival (Fig. 4A), indicating that larger differences in fecundity (a vital rate with lower sensitivity) between east and west outweighed smaller differences in survival (a vital rate with higher sensitivity). Black bears in eastern North America had a mean population growth rate of 0.99 (95%CrI: 0.96, 1.03), and mean population growth rate in western North America was 0.97 (95%CrI: 0.93, 1.01). However, growth rates of individual populations also varied considerably among studies within each half of the continent. Using among-study variance in vital rates as an estimate of among-population variation, the posterior density for individual population growth rates suggests that 55% of populations in the east and 34% of populations in the west have deterministic population growth rates >1 (Fig. 5).

DISCUSSION

At a large scale across North America, adult survival of black bears appears to trade off with reproductive rate. The eastern half of the continent showed increased reproductive rate, decreased adult survival, and younger age at maturity than the western half. The apparent east-west tradeoff may be accompanied by or confounded with a north-south cline because studies in the west were generally farther north

Table 4. Posterior mean vital rates and 95% credible intervals (CrI) for black bears in eastern and western North America, 1959–2007. From a Bayesian meta-analysis of demographic studies.

	Cub survival	Yearling survival	Subadult survival	Adult survival	Fecundity	Age at primiparity

than studies in the east. Trade-offs between reproduction and adult survival have been documented within other species as well as among species (Roff 2002). If most studies measured all vital rates, joint posterior distributions could be estimated to elucidate relationships among vital rates. However, few studies measured both reproductive rate and adult survival, and no correlation was apparent between them among those studies. It is possible that trade-offs occur in response to large-scale conditions, whereas other factors determine reproductive rate and survival at the population level. The apparent negative correlation at the continental scale could reflect differing habitat quality or differing mortality between eastern and western North America.

For example, following very poor hard or soft mast years, black bear reproduction often fails because mothers are in poorer condition going into winter dens (Eiler et al. 1989, Elowe and Dodge 1989). The differences between east and west could result from increased abortion of reproductive attempts or death of neonates due to poorer nutrition in the west. For differences in reproductive output to cause the observed tradeoff, the more frequent reproduction in the east

must extract a cost in terms of adult survival. Researchers have documented survival costs of reproduction for several mammals, including carnivores such as wolverines (*Gulo gulo*) and badgers (*Meles meles*; Clutton-Brock et al. 1983, Boyd et al. 1995, Woodroffe and Macdonald 1995, Persson 2005). However, other studies have failed to find measurable costs

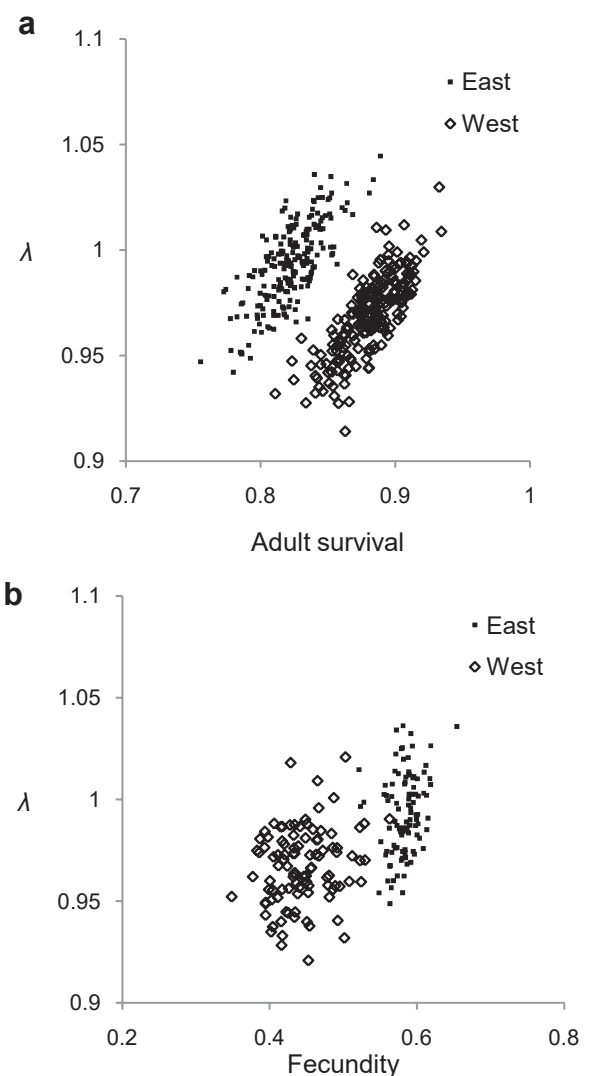

Figure 4. The relationship between estimated mean population growth rate and (a) mean adult survival and (b) mean fecundity from a Bayesian meta-analysis of female black bear vital rates in eastern and western North America, 1959–2007.

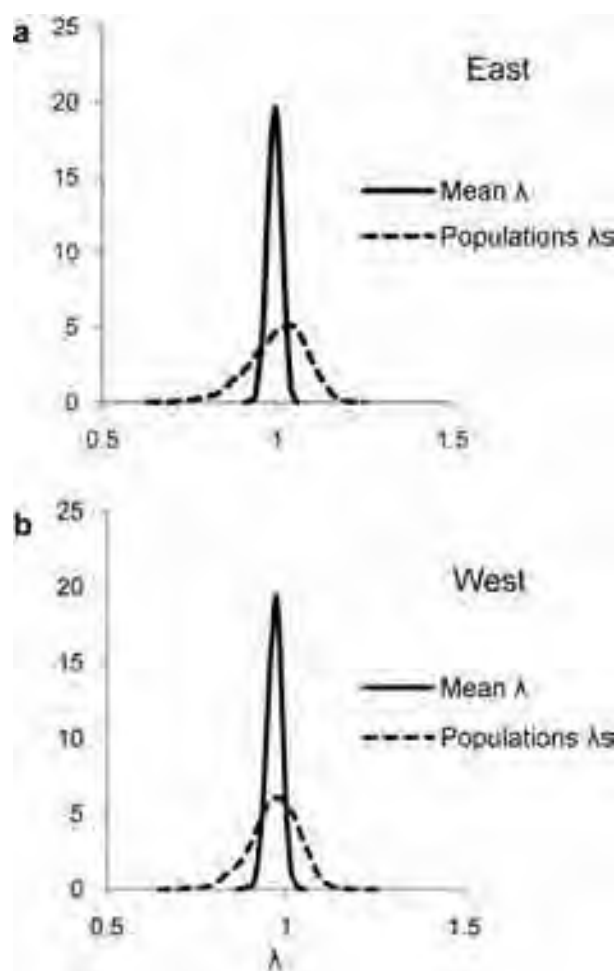

Figure 5. Posterior probability distributions of the mean population growth rate and the expected population growth rates of individual populations in (a) eastern and (b) western North America estimated from a post-birth-pulse matrix model using posterior probability distributions of vital rates from a Bayesian meta-analysis of black bear demographic studies across North America, 1959–2007.

of reproduction (Murie and Dobson 1987, Millar et al. 1992). Although to my knowledge no one has examined the costs of reproduction on adult survival in black bears, Atkinson and Ramsay (1995) found no apparent cost of reproduction on female polar bear (*U. maritimus*) survival.

Alternatively, increases in reproduction may be a response to decreased survival of adults. When life expectancy is shorter, animals should invest more in reproduction and less in survival. In hunted populations, harvest is the primary cause of mortality for adult black bears (Hellgren and Vaughan 1989, Schwartz and Franzmann 1991, Beringer et al. 1998, Koehler and Pierce 2005, Czetwertynski et al. 2007). Lower survival rates in the east suggest that these bears experience higher harvest and human-caused mortality, which would be expected from higher human population density in the east. Therefore, humans may be causing a shift in life history towards more and earlier reproduction by suppressing adult survival, both through harvest and non-harvest human-caused mortality like road kills and the removal of conflict bears. Shifts in life history and related

traits due to harvest have been observed in species with stage- or sex-selective harvests (Ericsson 2001, Coltman et al. 2003, Jorgensen et al. 2009), and increasing harvest mortality selects for younger age at maturity regardless of the selectivity of harvests (Allendorf and Hard 2009, Darimont et al. 2009). Evidence for compensation in individual populations of black bears is equivocal (Beecham 1980, Czetwertynski et al. 2007, Obbard and Howe 2008), and responses may be confounded with effects of habitat and density (Czetwertynski et al. 2007). Further work needs to be done to assess whether the observed pattern between adult survival and reproduction is mainly the result of differences in habitat, harvest and human-caused mortality, or not an actual trade-off but a combination of these factors.

Black bears are long-lived with low reproductive rates, and as expected, adult survival had the highest elasticity. However, population growth rate was higher in the east, suggesting that differences in fecundity outweighed differences in adult survival. Generally, the vital rate with highest elasticity is expected to have low variation (Gaillard et al. 1998, Pfister 1998, Wisdom et al. 2000), and in this case the low spatial variation of adult survival decreases its importance for population growth rate. Elasticity rankings do not necessarily correspond to a vital rate's role in determining population growth rate (Wisdom et al. 2000). Importance of higher fecundity for higher population growth rates in the east mirrors other black bear studies showing that higher temporal variation in reproduction renders it most important in determining population growth rate (Beecham 1983, Mitchell et al. 2009). Unlike my results, Beckmann and Lackey (2008) found that an urban black bear population with higher fecundity and lower survival had a lower population growth rate than a wildland population. However, adult survival in the urban population was suppressed beyond its normal range due to human activities, essentially artificially increasing the spatial variation in the most elastic vital rate.

The mean population growth rates indicate that bear populations are probably stable in the east and may be slightly declining in the west, counter to the general perception of managers that populations are increasing (Garshelis and Hristienko 2006, Hristienko and McDonald 2007). Out of 11 provinces and 33 states, only two reported population decreases between 1988 and 2001 (Hristienko and McDonald 2007). It may be that actual growth rates are in the right sides of the credible intervals, at or above 1, and there is no real discrepancy between perceptions and reality. Bias in the areas studied could also affect estimates because studies are not spread evenly across bear range or representative of the proportion of bears living in any given habitat. Moreover, many of the studies are decades old and may be outdated. Alternatively, increasing public sightings and complaints driven by an expanding human population could be masking stability or slow declines in bear populations (Garshelis and Hristienko 2006, Lambert et al. 2006). Researchers in several areas have indeed found that local black bear populations appear to be overharvested (Kasworm and Thier 1994, Powell et al. 1996, Brongo et al. 2005, Clark

and Eastridge 2006). Finally, it is also possible that movement from populations that are increasing may be subsidizing populations that would otherwise be declining (Hebblewhite et al. 2003). Even in the west, where the mean population growth rate is <1 , 34% of populations were estimated to be growing and could act as sources. Beckmann and Lackey (2008) propose that wildland bears are acting as a source for urban bear populations in Nevada, and bear sanctuaries like Pisgah in the southeast have been established with the intention of providing source populations for surrounding hunted populations (Powell et al. 1996).

MANAGEMENT IMPLICATIONS

Black bears are a charismatic species, and managers and conservationists face conflicting goals of ensuring population persistence and minimizing human–bear conflict. Achieving both of these goals requires information on population growth. Because growth rates are close to 1, small inaccuracies in vital rate estimates could lead to incorrect conclusions about whether the population of interest is increasing or declining. Due to the apparent spatial variation, borrowing demographic information from other studies, especially from the opposite half of the continent, will introduce bias. However, my results provide probability distributions of vital rates that allow managers to incorporate uncertainty explicitly, perform sensitivity analyses, and target future work at the most important gaps.

General patterns are apparent in black bear life history at a broad scale, and despite black bears' slow life history, their fecundity appears to be critical in determining population status. Vital rate variation among populations easily straddles the boundary between persistence and decline. Discrepancies between these data on black bears and our perceptions of population trend raise a red flag. Other data sources, including traditional mark–recapture and radio–telemetry, non-invasive DNA mark–recapture, and harvest information, can help assure us that our indices of population status are accurate. Moreover, the tradeoff between reproduction and adult survival deserves further exploration to determine the mechanism and implications for population persistence. Research examining the costs of reproduction on survival may help elucidate physiological tradeoffs, and further work clarifying compensatory responses of harvested populations may reveal the role of increasing adult mortality in the relationship, which would allow managers to more accurately predict the effects of harvest and protected areas on populations.

ACKNOWLEDGMENTS

I thank the many individuals and agencies that provided information for this analysis, including: T. Berens, Northwest Territories Environment and Natural Resources; W. Bolduc, R. Cross, and J. Vashon, Maine Department of Inland Fisheries & Wildlife; K. Bunnell, Utah Division of Wildlife Resources; K. Burgess, New Jersey Division of Fish and Wildlife; J. Cardoza, Massachusetts Division of Fisheries & Wildlife; K. Cartwright, Arkansas Game and Fish Commission; H.

Abstract: Harvest data provide readily available and relatively inexpensive information about populations of game species. However, these data are not necessarily representative of standing populations and may have limited applicability in management. We applied a method of harvest data analysis based on the changing sex ratio of the harvest with age to American black bear (*Ursus americanus*) harvest data from 1985–2005 in Montana. We assessed the ability of this method to identify assumption violations and the extent of resulting bias. A change in the relative vulnerability of females at primiparity due to protection of mothers with cubs from harvest was observable as a drop in the proportion of females in the harvest at the age of maturity. A changing harvest rate produced changing harvest rate estimates, but the estimates lagged up to 10 years behind the actual rate. Other assumption violations, such as unequal non-harvest mortality between sexes and stochasticity in the harvest rate, are not apparent in the harvest data themselves. If total harvest is known and the harvest rate is estimable, it may be possible to use harvest to identify population declines. However, we found with simulations that, in many cases, 10–15 years of harvest data are needed to identify a statistically significant decline. If all assumptions are met, we estimated harvest rates in Montana as 4.6% for females and 10.4% for males; these are overestimates if males have higher non-harvest mortality than females. Montana's harvest data did not show an apparent decline in the relative vulnerability of females at maturity, despite nominal protection of mothers accompanied by cubs. Analyses of harvest data also contradicted the hypothesis, based on meta-analysis of demographic data, that black bears were declining in Montana.

Key words: American black bear, catch-at-age, harvest, Montana, population trend, relative vulnerability, sustainable harvest, *Ursus americanus*

Wildlife managers are often charged with managing populations of game species that are rare or secretive, such as many furbearers and carnivores, using very limited resources. Many jurisdictions require hunters to bring harvested individuals through check stations where age and sex data are collected (Rupp et al. 2000), and in many cases, harvest data are the best or only source of information about the status of these populations. A variety of techniques, relying on different assumptions about population and harvest processes, can be used to estimate both harvest rates and population status or vital rates from these harvest data (Skalski et al. 2005). However, it is surprisingly common for

harvest data to be collected and not used or applied to management. For instance, in eastern North America, just 13 out of 26 jurisdictions that have a legal American black bear hunt used harvest data to estimate population size in 2011 (Noyce 2011). Likewise, Rupp et al. (2000) found that while almost all surveyed jurisdictions collected white-tailed deer (*Odocoileus virginianus*) harvest data, fewer than half of them used the harvest data for population models. Four respondents stated that harvest data were collected but not actually used in decision-making, and most of the agencies used harvest data to estimate the total harvest but not harvest rate or population size and trend (Rupp et al. 2000). More generally, harvest management is often developed from a patchwork of interests and implemented piecemeal over a sometimes long time

³Present address: Truman State University, Kirksville, MO 63501; julie.beston@gmail.com

frame (Milner-Gulland and Rowcliffe 2007), making application of harvest data in decision-making that much more idiosyncratic. Basing decisions on harvest data may also not be a top priority when managers must consider budget priorities and constraints and incorporate public interests and input.

One reason harvest data are not used more thoroughly may be the limitations of available harvest data analysis methods. Methods with various assumptions and requirements have been used to estimate harvest rate and population status from harvest data (Roseberry and Woolf 1991). Methods such as population reconstruction and change-in-ratio use the age and sex structure of the harvest to infer information about the population. Others, such as index removal and catch per unit effort, rely on combinations of surveys and harvest data. Roseberry and Woolf (1991) reviewed 9 methods and reported that half require data in addition to information on the harvested animals, such as harvest effort or a concurrent field study. Managers often lack such auxiliary information. Of methods that do not require auxiliary data, several use the age structure of the harvest to infer information about survival rates or population trend (Skalski et al. 2005). However, the composition of the harvest may not be representative of the living population (Litvaitis and Kane 1994), and the relative numbers of different ages may reflect hunter selectivity, age- and sex-specific vulnerabilities to harvest, or the effect of harvest regulations more so than the population trend (Bunnell and Tait 1980, Noyce and Garshelis 1997). Estimates of harvest rates derived from harvest data are also more reliable when a large proportion of the population is removed each year (Harris and Metzgar 1987, Roseberry and Woolf 1991), which is thought not to be the case for many carnivores.

In this paper, we examined the robustness of a combination of the methods presented by Paloheimo and Fraser (1981) and Fraser (1984) for estimating harvest rate of black bears. The method we applied avoids some problems of other methods, such as the need for additional data, and explicitly models the differential vulnerability to harvest across groups. However, information on hunter effort is needed if it has not been constant, and the method we used relies on a number of assumptions: the initial sex ratio is even, the differential vulnerability of the sexes is constant across ages, the harvest rate is constant

across time, and the natural mortality rates are equal for both sexes. Assuming these are met, if one sex is more vulnerable to harvest than the other, the ratio of males to females in sequential harvests of a cohort will change as that cohort ages. Fraser (1984) showed that the inverse of the age at which the sex ratio of the harvest is even will approximate the average harvest rate. This simple estimate works best when the harvest rate is near 0.5 or the differential vulnerability is much less than the harvest rate. Paloheimo and Fraser (1981) used the same principle, but relaxed these requirements by using generalized least squares to estimate harvest rate and relative vulnerability using a model of harvest sex ratio at each age. Harris and Metzgar (1987) explored the utility of these methods for bears in general and especially grizzly bears (*Ursus arctos*), and found that violations of the assumptions biased estimates of harvest rate more when the harvest rate, differential vulnerability, or both were low and when harvest samples are small.

In many jurisdictions, black bear harvests exceed the samples simulated by Harris and Metzgar (1987) by an order of magnitude or more, meaning the method may be more appropriate for black bears than initially suggested. We used stochastic simulations to not only explore how assumption violations bias harvest estimates, but also to assess qualitatively whether the harvest data can indicate when assumptions are violated. We then applied the method to harvest data for black bears in Montana and examined the expectation that adult female black bears experience lower harvest than immature females because it is illegal to harvest a female when she is accompanied by young. Our expectation was that the vulnerability of female black bears in Montana decreased by 50% at primiparity because adult females spend about half their time accompanied by cubs (Mace and Chilton-Radandt 2011).

When total harvest is known, it is possible to estimate the population size based on harvest rate estimates. We used simulations to determine whether we would be likely to detect population declines under constant harvest rate using total harvest and estimated population size. We then applied this concept to Montana's black bear harvest data to evaluate the hypothesis that black bears were declining in Montana, an unexpected result from a meta-analysis of demographic studies (Beston 2011). The meta-analysis indicated that, on average, black bears were declining in the western United States, at

a rate of ~1–4%/year. This contradicted the general perception of managers that black bears were stable or slowly increasing throughout their range (Garshelis and Hristienko 2006). The conclusion that populations were declining could result from biases in data available for meta-analysis, but it could also mean that our impressions of growth were incorrect (Garshelis and Hristienko 2006, Lambert et al. 2006). Harvest methods and tag sales have been consistent in Montana for the past 20 years (R. Mace, unpublished data). Therefore, if the black bear population was declining we predicted that the harvest rate was increasing and the total harvest was stable, that the harvest rate was stable and the total harvest was decreasing, or some combination of increasing harvest rate and decreasing total harvest.

Black bear hunting in Montana

In Montana, black bear range is restricted to the mountainous western portion of the state, and hunting is permitted in all 5 Montana Fish, Wildlife and Parks (MFWP) regions where black bears occur. Bears were hunted in 2 seasons: in spring from April 15 through mid-May–mid-June, and in fall from September 15–late November. Black bear licenses for residents cost \$15–19 and permit the take of 1 black bear/calendar year. Hunting bears using bait or dogs has been illegal in Montana since the first half of the twentieth century. It was also illegal to harvest cubs (black bears <1 year old) and mothers with young. Because family break-up occurs during the summer, a female with yearlings was illegal to harvest in the spring but legal to harvest in the fall of the same year. In addition to direct protection when accompanied by cubs, females tend to enter hibernation earlier and remain in hibernation later than males, especially when pregnant or nursing (Beecham et al. 1983). They may be in dens by mid-October and remain until late May (Jonkel and Cowan 1971, Beecham 1983), missing most of both hunting seasons. Tag sales in Montana were relatively constant for the 20 years prior to this analysis (MFWP, Helena, Montana, USA, unpublished data), and evidence from hunter surveys suggests the harvest effort, measured in hunter days, was consistent for the period for which data are available (MFWP, Helena, Montana, USA, unpublished data, 1996–2003). Therefore, we did not include hunter effort in our estimation approach. Hunters were required to bring harvested black bears

through check stations, where each bear was sexed and a tooth collected for aging. Based on the call-back survey, check station compliance was believed to be nearly complete, and thus we used the numbers of bears brought through check stations as the total harvest size.

Methods

Estimation of harvest rate

Given an average harvest rate of k and a difference in vulnerability $2v$, such that the harvest rate of males is $k+v$ and the harvest rate of females is $k-v$, then the ratio of males in the harvest, H_m , to females in the harvest, H_f , at age i can be written as

$$\frac{H_{m,i}}{H_{f,i}} = \frac{M_1(1-(k+v))^{i-1}s_m^{i-1}(k+v)}{F_1(1-(k-v))^{i-1}s_f^{i-1}(k-v)},$$

where M_1 and F_1 are the numbers of males and females, respectively, in the cohort when it enters the harvestable population, and s_m and s_f are the natural survival rates of males and females. This is essentially the same equation used by Paloheimo and Fraser (1981), replacing their vulnerabilities and hunter efforts with constant harvest rates.

Two methods can be used to estimate k and v based on this equation. We took the natural logarithm of both sides and used generalized least squares estimation to find k and v , following Paloheimo and Fraser (1981). Alternatively, we used regression to estimate the age when the harvest sex ratio is 1 and coupled this with information from the youngest harvest age to create a system of 2 equations. We then solved these equations for the 2 variables, which was essentially the approach used by Fraser (1984). At the youngest age of harvest (1 year old for black bears), the sex ratio of harvest can be written:

$$\frac{H_{m,1}}{H_{f,1}} = \frac{M_1(k+v)}{F_1(k-v)},$$

and at age y , the male and female harvests are equal, yielding:

$$1 = \frac{M_1(1-(k+v))^{y-1}s_m^{y-1}(k+v)}{F_1(1-(k-v))^{y-1}s_f^{y-1}(k-v)}.$$

Note that we assumed $M_i = F_i$ and $s_m = s_f$ in order to solve for y . We found that both methods produced

similar results, so we present results from the latter method.

Analysis of assumption violations

We used simulations to assess the effects of assumption violations on the structure of the harvest data and the resulting estimates of harvest rate. For each analysis, we simulated 2,500 replicate stochastic populations for 20 years using a 60 x 60, pre-birth pulse, sex and age-based matrix model (Caswell 2000). Bears were divided into 4 stages: cubs (0 years old), yearlings (1-yr), subadults (2–5 yr), and adults (6–30 yr). Males and females had the same survival rates, except in simulations that specifically considered deviations from equal natural mortality. Adult females produced cubs in a 1:1 sex ratio. We parameterized the model with survival rates and variances from the western half of North America (Beston 2011). Harvest rates for each sex, fecundity, and their variances, as well as age at primiparity, were based on data from Montana. Each year a harvest rate for each sex was selected from beta distributions with mean equal to the initial estimates from Montana's harvest data and variance based on the variance seen in the total harvest assuming constant population size. After simulating harvest, vital rates were selected from beta distributions for survival, and a lognormal distribution for fecundity and the population was multiplied by that year's matrix model.

One assumption made when using the method described above to estimate harvest rate is that the relative vulnerability of the sexes does not change as a cohort ages. In Montana, however, we expected the relative vulnerability of female black bears to decrease at primiparity because mothers accompanied by cubs are illegal to harvest. To assess biases due to varying relative vulnerability, we simulated populations with adult females harvested at half the rate of subadult females. We assessed whether the resulting harvest data could indicate that the assumption had been violated and compared estimated rates of harvest with the actual total female harvest rate.

Application of this method of harvest rate estimation also assumes that the natural mortality is the same for both sexes. Male black bears may have higher natural mortality than female black bears, especially as subadults (Hellgren and Vaughan 1989, Koehler and Pierce 2005). However, some studies have failed to find a significant difference

between the mortality rates of males and females (Kasworm and Thier 1994, Wooding and Hardisky 1994). Results are also confounded because harvest mortality is included in most mortality estimates (Hellgren and Vaughan 1989, Kasworm and Thier 1994, Wooding and Hardisky 1994, Koehler and Pierce 2005). We simulated populations as above, with male natural mortality equal to up to 130% of female natural mortality, and assessed bias in harvest estimates and changes in harvest sex- and age-structure to determine whether violations of this assumption are apparent in the harvest data themselves.

Another assumption that many harvest data sets may violate is that harvest remains constant across the years analyzed. Two types of violations, stochasticity and trends in survival and harvest rates, can affect results. If there are no temporal trends, combining several years of harvest information should ameliorate the annual variability and increase the precision of estimates. To assess how the length of harvest dataset affects the precision of estimates of harvest rate, we conducted stochastic simulations of harvested populations using the model described above. We estimated harvest rate from the harvest age and sex structure beginning in year one. For each consecutive year, we estimated harvest rate using the sums of all bears harvested to date in each age and sex class.

When harvest rates changed, Harris and Metzgar (1987) pointed out that annual harvest estimates lagged several years behind. Their analysis explored a change from a stable population harvested at 5% to a 10% harvest rate, or vice versa. To explore the effect of a more continuous trend on the data structure and the resulting bias in harvest estimates, we conducted simulations with an increasing trend in the harvest rate over a 20-year timeline. We assessed the resulting harvest age and sex structure and the length of lag in the harvest rate estimates.

Using harvest to detect declines

If the harvest rate can be estimated and the total harvest is known, this information can be used to calculate population size through time. However, due to stochasticity and variation in harvest rate estimate, the power to detect changes in population size may be low. To assess the ability of abundance estimates derived from harvest data to reflect population declines, we used the above simulation harvested at 4% for females and 8% for males to

assess the power to detect a statistically significant decline in total population size as the length of the harvest dataset increased. Additionally, because managers sometimes lack information on the sex and age structure of the harvest, we also assessed the power to detect a statistically significant decline in total harvest from these simulations as an index for population size.

Initial population sizes were 10,000, 30,000, and 50,000 bears, which covers the likely range for Montana's actual black bear population size based on the estimated harvest rates (see Results) as well as the best guess of managers as of 2001 (Hristienko and McDonald 2007). For each simulation, we fit a linear regression to either the estimated total population size or the total number of bears harvested each year, starting with 3 years of harvests and adding consecutive years through the end of the dataset. Each year, we checked for a statistically significant decline by assessing whether the coefficient of year was <0 ($P = 0.05$). This is likely a conservative scenario because the spatial variation incorporated in population growth rate (via vital rate distributions from Beston [2011]) probably overestimated the temporal variation in any one population (because management and habitat varied widely among populations across western North America).

Montana black bear data

We estimated the harvest rates for male and female black bears in Montana using the method described above. We estimated y , the harvest in which the sex ratio is 1:1, using black bear harvest data collected in Montana from 1985–2005. We assumed low natural mortality over the winter (Hebblewhite et al. 2003) and combined the fall harvest with the following spring harvest to calculate the total harvest for each age class. To find y , we first summed each age class over the entire 20 year harvest dataset, and regressed y_i (proportion of females in the harvest) against i (age). We weighted the regression by total bears harvested at each age to account for smaller sample sizes at older ages. We solved the regression equation for 50% females in the harvest to estimate y and used y to estimate harvest rate.

We used qualitative comparisons of the structure of the harvest data to determine whether the assumption of constant relative vulnerability between sexes was violated. We also assessed the

potential bias in differences in natural mortality by calculating male and female harvest rates using the Montana estimate of y and varying the ratio of male mortality to female mortality, $(1-s_m)/(1-s_f)$, from 1 to 1.1. We were specifically interested in the case where male mortality was higher than female mortality, the most likely situation for black bears, and quantified the bias separately for male and female harvest rates.

To assess possible trends in Montana's harvest rate, we estimated annual harvest rates using the age and sex structure of each year's harvest. We also estimated harvest rates using non-overlapping 5-year sets to increase precision of estimates. We used the estimated harvest rates through time to estimate population size. Finally, we examined the total population size estimates and the total harvest to determine whether the population appeared to be decreasing.

Results

Analysis of assumption violations

Simulations in which adult females were harvested at half the rate of subadult females produced a noticeable break in both the proportion of females harvested and in the number of females harvested at each age (Fig. 1). If the relative vulnerability of females decreased at age of primiparity, the proportion of females in the harvest at that age dropped, and if total vulnerability decreased, the total number harvested dropped. In this scenario, the average estimated female harvest rate (2.72%) underestimated the actual simulated harvest rate of adult females (3.05%) by about 10%. Other simulations were explored with varying violations of this assumption, with the same general result.

The sex and age structure of the harvest when male natural mortality was greater than female natural mortality was not distinguishable from a scenario with a greater harvest rate and equal adult survival for both sexes. Increased male mortality resulted in an overestimation of both male and female harvest rates (Fig. 2).

An increase in the number of years incorporated in the estimation yielded more precise estimates of the harvest rate. Given the levels of variance seen in black bear vital rates across the western half of their range, much improvement was gained in the first 5 years of data gathering (Fig. 3). The

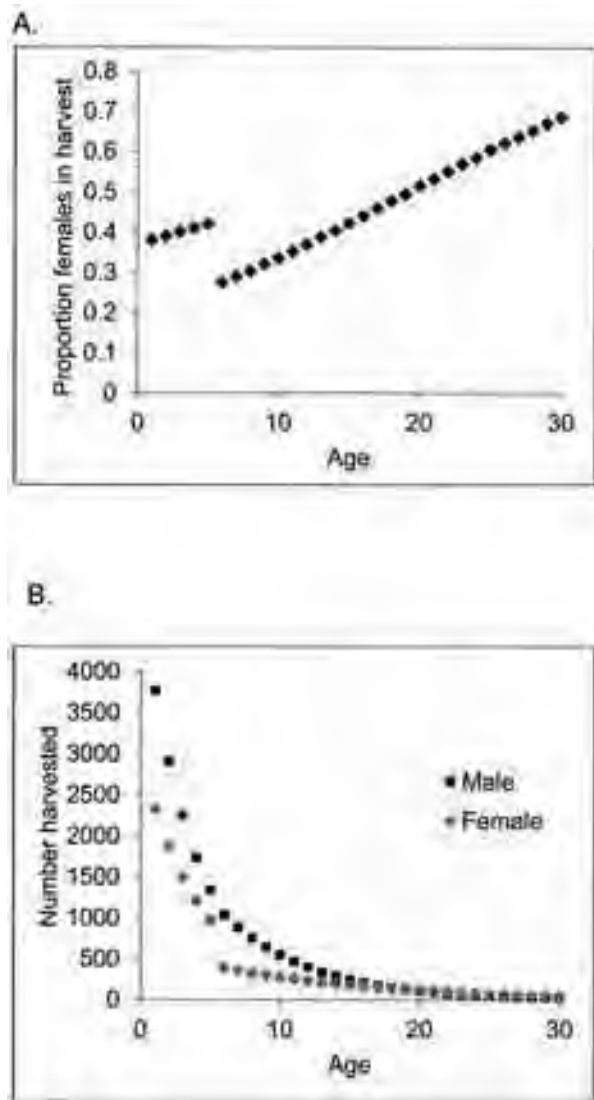

Fig. 1. Proportion of females in the harvest by age (A) and total harvest by age (B) in a simulated western American black bear population in which adult female vulnerability to harvest decreases by 50% at the age of primiparity.

inter-percentile ranges in the estimate of harvest rate leveled out after about 15 years. Populations experiencing lower levels of variance would require fewer years to gain similar precision in harvest rate estimates.

Simulations indicated that estimates of harvest rate lagged as much as 10 years behind actual changes in rates (Fig. 4). The age structure of the harvest data, however, did not change over time as harvest rate changed, and was therefore not helpful in indicating a violation of this assumption. The sex

ratio of the harvest at young ages (1–4 yrs) did not change over the 20-year timeline, but the proportion of females in the harvest at older ages, especially 10–20 years, changed by about 1%/year. This change was much smaller than the variation among the

Fig. 3. Average estimates of male and female American black bear harvest rates and associated inter-percentile range from 2.5–97.5% in 2,500 simulated western populations as an increasing number of years of simulated data were combined in the harvest rate estimations.

simulated populations and was therefore also not helpful in indicating a violation of this assumption.

Using harvest to detect declines

Given the estimated harvest rate and variation in Montana (described below) and the population growth rate and variance for western North America, a decline in the population was observed in the harvest in 80–86% of simulations after 15 years of harvest data collection (Fig. 5). Only 44–80% of the population estimate series showed statistically significant declines after 15 years of harvest data collection (Fig. 5). Larger population sizes produced larger harvests, better estimates of total population size, and greater power to detect declines.

As the population growth rate approached 1, the number of years required to reach 90% power in detecting declines using only the harvest numbers increased dramatically (Fig. 5B). Populations decreasing at 1–5% a year were reliably identified with 10–20 years of harvest data; annual decreases of less than 1% a year took considerably longer to detect. After 5 years, only 20% of the most rapidly declining populations, $\lambda = 0.95$, displayed statistically significant declines in the harvest numbers.

Montana black bear data

The R^2 of the regression of proportion females in Montana's harvest from 1985–2005 against age was

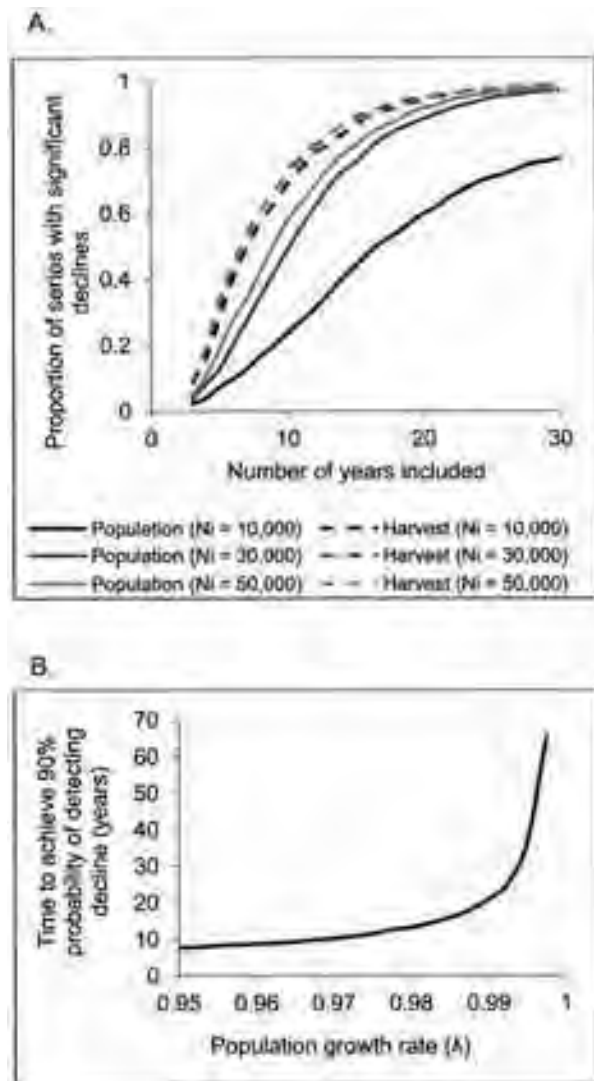

Fig. 5. Estimate of the proportion of simulated American black bear populations in which a statistically significant negative trend was identified in the estimated population size or the total number of bears harvested through time (A) and the time it took to achieve 90% power to detect decline using total harvest numbers of simulated unstructured populations (B).

0.94, and the estimated value of y , the age at which males and females are equally represented in the harvest, was 14.2 years (Fig. 6). The high R^2 value implies either that the basic tenets of this model were borne out by Montana's data, or that biases created by assumption violations were in opposite directions and canceled each other out. The estimated annual harvest rates for male and female black bears in Montana were 10.6% and 4.3%, respectively, given

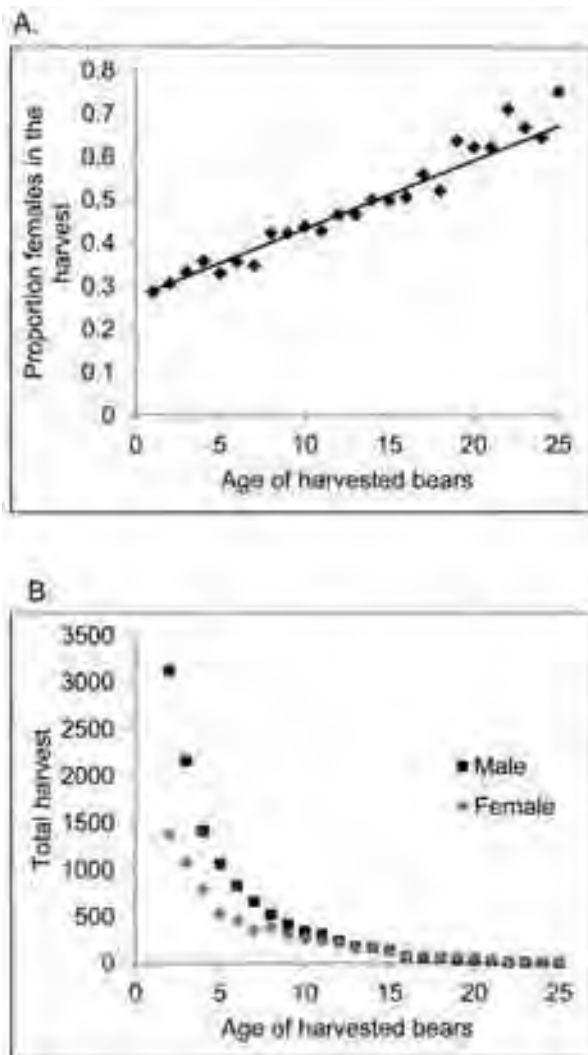

Fig. 6. The proportion of female American black bears by age (A) and total harvest of female black bears by age in Montana's harvests (B), 1985–2005.

an initial sex ratio of 1, constant relative vulnerability of the sexes, equal natural mortality rates for males and females, and constant harvest rate through time. These estimated rates are an average across the state and most representative of the harvest rates in western Montana, where the largest harvests occur, rather than the harvest rates in the sparser populations in central Montana.

Montana's proportion of females in the harvest was not consistent with expectations based on reduced relative vulnerability at primiparity (Fig. 6). At the age when vulnerability changed in the simulations, a break was noticeable in both the proportion of

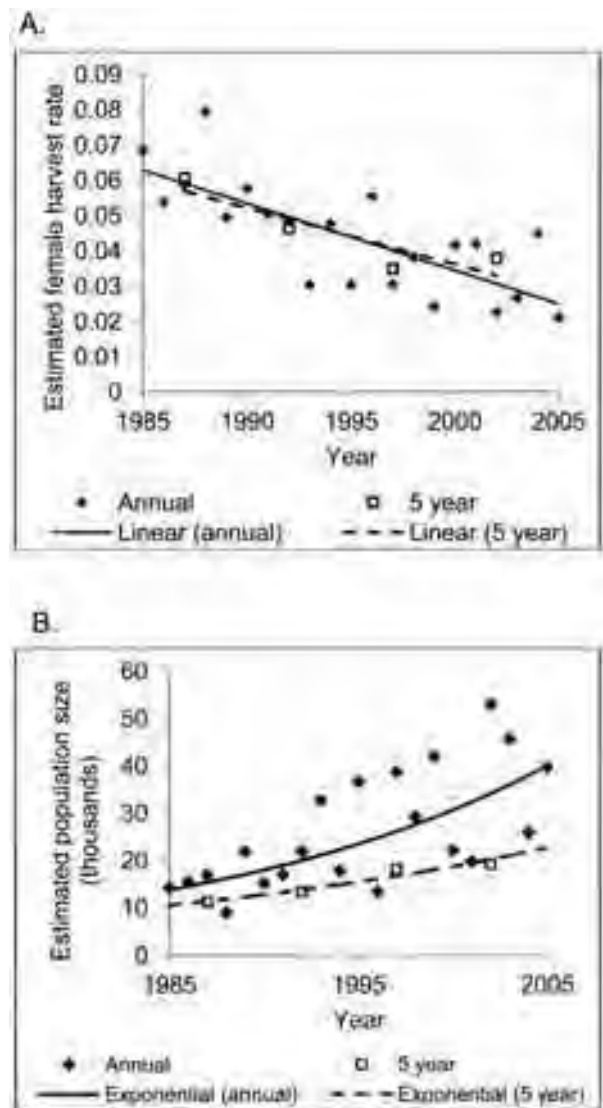

Fig. 7. Annual and 5-year pooled estimates of female American black bear harvest rate (A) and black bear population size (calculated as total male harvest/estimated male harvest rate + total female harvest/estimated female harvest rate) in Montana (B), 1985–2005.

females harvested and in the number of females harvested at each age (Fig. 1).

Annual estimates of harvest rate and estimates using 5-year periods suggested a declining trend in Montana's harvest rate, with some autocorrelation evident in the annual estimates (Fig. 7). Estimates of population size calculated from annual harvest rates and pooled 5-year harvest rates and the reported total number of bears harvested each year

depicted a population that had risen from approximately 12,000 bears in 1985 to between 20,000 and 40,000 bears in 2005 (Fig. 7B), for an average annual population growth rate of approximately $\lambda = 1.05$.

Discussion

Though estimation of harvest rate from the sex and age of harvested individuals has several limitations, the method we applied can produce usable harvest rate estimates and information on population status or trend that can be applied in decision making. The confidence in these estimates is higher given more years of harvest data and lower temporal stochasticity. Our results supported the hypothesis that at least some assumption violations of Fraser's (1984) and Paloheimo and Fraser's (1981) methods can be identified by the harvest data themselves. Additionally, biases due to violations of assumptions in our simulations were generally less dramatic than those found by Harris and Metzgar (1987), likely due to much larger harvest samples. Furthermore, the expectations that Montana's black bear population was declining and that the relative vulnerability of females compared to males changed as bears reach adulthood due to the protection of mothers with cubs were not borne out by the data.

Examination of harvest data can reveal whether some of the assumptions needed for this method are violated. If the relative vulnerability of the sexes changes with age, a discontinuity will be present in the proportion of females in the harvest at the transition ages. If the absolute vulnerability of either sex changes with age, a discontinuity will be present in the total harvest of that sex at the transition ages. It is important that this violation is identified because it can lead to non-conservative underestimation of harvest rate if the relative vulnerability of females decreases at primiparity (our results, also Harris and Metzgar 1987).

We were unable to identify whether the assumption of equal natural mortality for both sexes was violated using harvest data. However, harvest rate estimates based on this assumption will be conservative when male mortality is higher than female mortality, which is likely true in a variety of mammalian and avian species (Promislow 1992, Promislow et al. 1992), because they will overestimate harvest rate. If these harvest rates are used to

estimate population size, they will underestimate population size.

Changing harvest rates will be apparent if annual sex and age structures are used to estimate yearly harvest rates, although the estimates will lag behind the actual value of harvest rate until it stabilizes. This generally agrees with the results of Harris and Metzgar (1987), which were based on scenarios where harvest rates changed between 2 seasons then remained constant rather than changing across all seasons in the time horizon. It is important to note that the age structure of the harvest data did not show an obvious trend, and the sex structure changed slowly in the adult age classes and not at all in the young age classes. It has been shown that age and sex composition of the harvest reflected relative vulnerability rather than population size or structure (Harris and Metzgar 1987, Garshelis 1990). Likewise, monitoring harvest via mean age or sex ratio alone is inappropriate. Despite this, Miller et al. (2011) point out that these sex and age ratios are still used inappropriately by managers to monitor populations.

It appeared unlikely that the vulnerability of female black bears to harvest in Montana changed dramatically at the presumed age of primiparity, and this contradicted our expectation that protection of females accompanied by cubs reduces the vulnerability of adult females (McLoughlin et al. 2005). Estimates based on reproductive tracts suggest adult females spend half their time accompanied by cubs (Mace and Chilton-Radandt 2011), which implies that vulnerability of adult females should be half that of subadults because females with young are illegal to take. Females are more likely to be accompanied by young in the spring than in the fall because family break-up occurs over the summer; thus, it is possible that the vulnerability to the spring harvest changes but the unchanged vulnerability and larger total harvest during the fall obscure that change. Alternatively, a greater proportion of young female bears could be producing their own cubs or accompanying their mothers or siblings than we expect, giving them as much protection as adults, or hunters could be taking females with cubs more often than previously assumed. If cubs are in trees or hiding as a hunter approaches, it may not be obvious to the hunter that the mother has young. Because bears are not baited or hunted with dogs, hunters may have less opportunity to observe young nearby than in jurisdictions where these methods are

allowed. Hristienko et al. (2004) estimated only a 2% orphaning rate for black bear cubs during spring hunts in Manitoba, but Montana's may be near 4% if protection of mothers with young is completely ineffective.

In Montana, harvest data show annual negative autocorrelation in harvest rate as well as a declining trend in the harvest rate, and this trend remained when 5-year periods were pooled to increase precision. Autocorrelation can be induced even by weak responses by managers to change quotas each year and can make populations more variable and susceptible to decline (Fryxell et al. 2010). Unless new information is available about the population status, it may be unwise to tinker with harvest quotas based solely on the number of individuals harvested the previous year. Because Montana's estimated harvest rate leveled out from 1997 onward, more recent estimates are probably more accurate.

The total number of individuals harvested may reflect changes in population size more accurately than estimates of total population produced by dividing the total harvest by the estimated harvest rate. This is likely due to the amplification of error that occurs when going from an estimated rate to an estimated population size. In either case, identification of declines lagged well behind changes in simulated population size, even when the population was declining relatively rapidly. Annual changes in environmental conditions, such as natural food availability, can affect the vulnerability of individuals to hunters (Fieberg et al. 2010), and the ability to detect changes in population size will depend on how variable that vulnerability is and how consistent harvest effort and methods are. Hristienko and McDonald (2007) suggested that occasional over-harvest of black bears will not be a problem because managers will respond rapidly to reduce harvest in subsequent years. The time lags apparent in both the decline of harvest numbers and the estimates of harvest rate indicate that managers may not be able to respond rapidly because they cannot discover the problem quickly enough.

It is encouraging that with more than 20 years of harvest data for Montana, we do not have evidence of a negative trend, let alone a statistically significant one. Indeed, annual estimates of harvest show that harvest rates have declined while the total harvest has been fairly stable. Because the same number of bears harvested represents a smaller proportion

of the population (the harvest rate), these results suggest the population has increased. This is consistent with the fact that our estimated rates (4.3% for females and 10.6% for males) are well below reported estimates of sustainable harvest rates for black bears (14.2% [Miller 1990], 15% [McLaughlin 1998], 21% [Klenzendorf 2002], 12.6% [Dobey et al. 2005]).

On its face, this contradicts our hypothesis, based on the meta-analysis of demography (Beston 2011), that black bears have been decreasing in western North America. The average population growth rate based on the demographic work was less than 1, but our present harvest analyses indicate that, if anything, the population was increasing. The actual growth rate may be in the right tail of the distribution (at or above 1), the demographic work could be biased, or there may be other processes occurring for which we have not accounted. Although demographic studies are often considered the gold standard, they are more limited in space and time and therefore may not be representative of the true population status across large geographic areas. Demographic studies included in the meta-analysis had a median sample size of about 30 bear-years (Beston 2011), and because adult female survival rates are close to 1 (0.88 in the west; Beston 2011), researchers might only observe 3 or 4 deaths over the course of such a study. The small sample sizes typical of bear demographic work reduce precision of resulting estimates and make added information from harvests even more valuable. Harvest data can provide another means of estimating population trends at large scales to check against intensive demographic studies at smaller scales. If the demographic work is concurrent with harvest data collection, it can be used as auxiliary information in a statistical catch-at-age analysis that uses the age structure of harvest and prior knowledge about demography to estimate harvest rate and population size (Gove et al. 2002).

Another possibility is that spatial structuring and source-sink dynamics allow growing populations to support those that would otherwise decline. Some regions rely on wildlife refuges and sanctuaries to boost populations subjected to harvest in surrounding habitats (Powell et al. 1996). The meta-analysis suggested about 34% of western populations were growing (Beston 2011), and these could serve as sources that allow bears to persist despite low population growth rates elsewhere. In Montana,

Glacier National Park provides protection from harvest, and black bears living deep in the Bob Marshall and other wilderness areas may be essentially inaccessible to most hunters. Further work needs to be done to determine the effect of these and other potential source habitats on surrounding populations.

In theory, the harvest rate estimation method we used can be applied to any game species with differential selectivity in the harvest for which we can collect sex and age data. Male-biased harvesting occurs in mammals with multi-annual parental care, such as bears and elephants (*Loxodonta africana*), when females with young are protected and when adult males are targeted as trophies (McLoughlin et al. 2005). It is also intentionally applied in some ungulate systems because females are considered the limiting component of the population (Ginsberg and Milner-Gulland 1994). In reality, harvests need to be large enough to overwhelm demographic stochasticity, and the nature and degree of assumption violations need to be explored. The largest biases and sensitivities to assumption violations for the method we used occur when harvests are small (Harris and Metzgar 1987). This method could also be extended to incorporate differing harvest rates and relative vulnerabilities for spring and fall harvest seasons and geographic structuring to analyze different regions or management units. Because we analyzed the state as a whole, our estimated harvest rates are probably most representative of the western part of Montana, where most black bears live and are harvested. Extensions would require harvest sample sizes in each season or geographic area to be large. Although this method can be applied in principle to many game species, other methods may be more appropriate in some situations. For example, if it is possible to couple field studies with harvest data in approaches such as statistical catch-at-age analysis, researchers can obtain more accurate information in fewer years (Gove et al. 2002). When management is consistent across years, the target species has a short life-span and simple age structure, or the harvests are relatively large (in the hundreds), the method we employed could be a valuable way to garner information about the target population.

Acknowledgments

Our thanks go to E. Crone, M. Mitchell, S. Mills, and V. Ezenwa for comments on an earlier version of

this manuscript. We thank the many individuals who helped gather the harvest data. Thanks also to 2 anonymous reviews and the editor for their comments and suggestions.

Population Dynamics of Bears —Implications

F. L. BUNNELL

D. E. N. TAIT

INTRODUCTION

Ursinus elmensis, the small "dawn bear" of about 20 million years ago, occurred in the (then) subtropical climate of southern Germany. Its living descendants are members of the *Ursus* line: the brown and grizzly bears (*Ursus arctos* Linne), black bears *U. americanus* (Pallas) and *U. thibetanus* (Cuvier), and polar bears *U. maritimus* (Phipps). Over the intervening millennia, these bears have evolved different shapes and sets of tactics. Many forms failed, most recently the cave bear (*U. spelaeus*) only a few thousand years ago. The living forms now extend over the northern hemisphere from about 25° to 88°N.

Here we examine the tactics of current members of the genus *Ursus* as employed in their pursuit of survival. Of the living forms, only *U. thibetanus*, for which data are very sparse, is not considered. We examine first the size of living forms, for body weight shows close relationships with reproductive behavior. We then consider observed patterns in reproductive rates and mortality. Phenomena influencing these patterns are considered in association with population regulation. Finally, implications of these patterns are addressed.

SIZE OF BEARS

Common conceptions of the size of bears are inaccurate (Burghardt et al., 1972). Black bears (*U. americanus*) are the smallest, mean weights of adult males range from about 80 to 150 kg, depending on location, and are usually 60 to 70% heavier than adult females (Table 1). The largest recorded weights are from the eastern United States [e.g., 272 kg from New York (Black, 1958), 264 kg from New York (Harlow, 1961)]. Brown and grizzly bear weights are most inflated in "conventional wisdom." Typically, adult males average about 200 kg and may be 20 to 80% heavier than females in the same population (Table 1). Most older records of massive brown bears are suspect (see e.g., Holzworth, 1930). Recent records of very large grizzly or brown bears are 386 kg from coastal British Columbia (D. Hebert, personal communication, 1975), 443 kg from the Alaskan Peninsula (Glenn, 1975), and 500-685 kg from Kamchatka

^a Fall (September-November) weights measured by facilitator compensation. ^b Numbers in parentheses are sample sizes. ^c Estimated from one section of the femur.

(Novikov 1969). Uncommonly heavy and well-fatted polar bears attain similar weights [464 kg from the Franz Joseph Archipelago (Parovchshikov 1964), 550 kg from Svalbard and Canada (Løng, 1970; Stirling et al. 1975)]. Pedersen (1945) reported a male bear weighing 800 kg. Generally, mean weights of polar bears are heavier than for brown or grizzly bears (Table 1). Adult males average about 280 to 350 kg and may be 60 to 100% larger than adult females (Table 1).

REPRODUCTIVE PATTERNS

Background

Members of the genus *Ursus* share a reproductive syndrome: collectively they exhibit some of the lowest reproductive rates among terrestrial mammals. Periodically, most of the population foregoes reproduction entirely (for polar bears, see data of Stirling et al. 1975; for black bears, Jonkel and Cowan, 1971; for brown bears, Martinka, 1974). The low reproductive rate occurs in spite of features that should encourage reproductive success. All North American *Ursus* are induced ovulators (Erickson and Nellor, 1964; Løng, 1970; Craighead et al. 1969). Induced ovulation normally encourages higher rates of fertilization (Brambell, 1948). All *Ursus* hibernate, although among polar bears, the phenomenon is largely restricted to parturient females. Lord (1960) noted that hibernators generally have smaller litter sizes than do nonhibernators and suggested that the smaller litter size was associated with higher initial survival rates for the young of hibernators. Compared with other mammals of equivalent size, bear litters are not small (Table 2). Nevertheless, realized rates of reproduction are low, primarily attributable to a late age of first reproduction and a long period (here termed *breeding interval*) between litters (Table 3). We believe the periodic failure of reproduction is adaptive and that it is assisted by another characteristic shared among *Ursus*: that is, delayed implantation (Dittrich and Kronberger 1963; Wimsatt, 1963; Craighead et al. 1969). Delayed unplantation likely provides an energetically efficient means of "aborting" the young before the demands of late gestation and lactation occur.

The denning habit, induced ovulation, and delayed implantation are common among members of *Ursus*. Demographic features that modify reproductive rates and that vary among the species are age of first reproduction, breeding interval, and litter size (see also Chapter 9). Black bears, the most primitive of the genus, most frequently have a mean age of first reproduction of 4 to 5 years, although it may be as late as 7 to 8 years (Table 3). Captive animals show somewhat earlier ages of first reproduction ranging from 3 years to 7 years (Rausch, 1961; Stickley 1961; Rogers, 1976). Mean litter sizes in the wild range from 1.32 to 2.4 or more, with a mean of 2.25 ($n = 516$ family groups). Data are sparser for breeding interval. Eastern populations with energy-rich mast and berries as forage may breed every two years (Erickson, 1964; Free and McCaffrey 1972; Pelton and Beeman, 1975) while western populations appear to have a mean breeding interval of slightly more than three years (Table 3).

^a Our calculations from data provided.^b Cubs taken from mother.

The larger grizzly matures more slowly, and mean age of first reproduction is more commonly one year later, at age 5 to 6 years. The northernmost populations in the interior of the Yukon and Alaska mature still later, at 7 to 8 years or older (Pearson, 1972; Reynolds, 1976). Modal litter size among grizzlies ranges from about 1.8 to 2.2 (mean 2.12, $n = 1042$ family groups), and mean breeding interval appears to be about 3.5 to 4 years (Tables 2 and 3). Although much larger than the black bear, female polar bears become sexually mature at about the same age (Table 3). Mean breeding interval appears to be from 3 to 3.5 years, but litter sizes are considerably smaller (mean 1.76, $n = 916$ family groups).

Model

Together, the age of first reproduction, litter size, and breeding interval determine the population's reproductive rate. Combining these appropriately into a simple model generates the maximum mortality that a population could sustain. The model assumes constant mortality rates and that cubs die only when the mother dies. The mortality rate essential to generate a stationary (nondeclining) population is balanced against the natality rate (see Bunnell and Tait, 1980). Figure 1 illustrates isoclines of the maximum sustainable mortality for populations having different average natality rates and ages of first reproduction. The natality rate is for reproductive females and is computed by dividing average litter size by the mean interval between reproduction, the breeding interval. This formulation facilitates comparison of black, brown, and polar bears.

For example, a brown bear population, in which females first breed at age 6.5, first reproduce at age 7, have a mean litter size of 1.5, and breed every three years (natality rate 0.5 cubs/year), can sustain no greater mortality than 10.7%/year (Figure 1).

Discussion

As a result of their higher natality rates, black bears can sustain the greatest mortality (Figure 1). The highest rates, 22 to 24%, are those computed from data for captive bears (Baker, 1912) from which cubs were removed and lactation-induced anestrus terminated, and for wild bears enjoying abundant forage (Rogers, 1976, 1977). Although natality rates for grizzly bears differ little from those of polar bears, their later age of sexual maturity generates a lower sustainable rate of mortality. The results have clear implications to managers establishing harvest policy, for they represent optimistic estimates of maximum sustainable mortality. They are also congruent with expectations derived from natural mortality patterns in *Ursus*. All bears are subject to mortality from conspecifics and man. In addition, black bears are killed by grizzlies (Jonkel and Cowan, 1971), by wolves (Schorger, 1949; Rogers, 1977), and even by coyotes (Boyer, 1948). Grizzlies seem to have no predators beyond man and conspecifics.

Figure 1 Isoclines of maximum sustainable mortality (%/year) as a function of average age at first reproduction and average natality rate (litter size/years between litters) Grizzly bears, \square polar bears, \blacktriangle black bears, \bullet captive populations, c.

(see chapter 9) although Ognev (1931) Averin (1948) and Pulliainen (1963 1972) have reported instances of wolves attacking brown bears in Eurasia, and Murie (1944) and G. G. Haber (personal communication, 1978) reported wolf attacks on grizzlies in Alaska. Polar bears have no predators beyond conspecifics, but have been killed by their intended prey both walrus (*Odobenus rosmarus*) and hooded seal (*Cystophora cristata*) (Lønø, 1970). As predators, polar bears sometimes experience a serious reduction in prey availability—for example, when ice conditions are unfavorable for hunting seals (Stirling et al. 1975). Thus, we expect and observe higher sustainable rates of mortality than for grizzly bears.

Mean litter size of polar bears is smaller than for grizzlies (Table 2) as we would expect given their obligate, carnivorous nature. The higher realized natality rate is achieved by a lower mean age of first reproduction, despite the fact that the polar bear is larger than the grizzly (Table 1). Female polar bears, however, attain adult weight by age 3.5 years (Lønø, 1970; Stirling et al. 1977a) while female grizzlies require 6 to 7.5 years (Glenn, 1973; Reynolds, 1976).

The rather tight crescent of realized natality shown in Figure 1 suggests that both age of first reproduction and litter size are jointly influenced. Litter sizes are never large when age of first reproduction is late (despite potential advantages), nor is the reverse true. Nutrition is implicated and is discussed in association with population regulation. It is noteworthy that the obligate carnivore, polar bear, exhibits the least flexibility in realized reproductive rates.

MORTALITY PATTERNS

All *Ursus* appear to have similar life spans in the wild. The oldest female polar bears observed have been 25 years old (Stirling et al. 1975; Lentfer et al. 1980). Brown and grizzly females may have a somewhat greater longevity: 28 to 30+ years (Couturier 1954; Storer and Tevis 1955; Pearson 1975). The oldest specimens of free-ranging black bear females are equally aged (a 27-year-old reported by Poelker and Hartwell (1973) and a 32.5-year-old reported by Sauer (1975). Females maintain their reproductive competency almost throughout their life span. The oldest reproductively active females reported in the literature are 21 years (Lentfer et al. 1980) and 23 years (Stirling et al. 1977b) for polar bears, 22 years (Nagy and Russell 1978) and 24.5 years (Pearson 1975) for brown bears, and 27 years (Poelker and Hartwell 1973) and 32.5 years (Sauer 1975) for black bears. Despite the similarity in maximum longevity between species, realized natality rates (Table 3) suggest broad patterns in the mortality rates of *Ursus*. Specifically, brown bear females should experience less mortality than do black or polar bear females (Figure 1).

We consider three stages in the life history of *Ursus*: cub, subadult, and adult. The cub phase lasts while the animal is under the protective care of its mother. This period varies within and between species (Table 3). Generally, black bears are self-sufficient at 1.5 years of age (range: 0.5 to 2.5 years), brown bears at 2.5 years (range: 1.5 to 4.5 years), and polar bears at 2.5 years (range: 1.5 to 3+ years) (see review of Bunnell and Tait 1981). Cubs generally are not hunted and their mortality rate can be estimated from changes in numbers through time without invoking the impacts of hunting. Bunnell and Tait (1981) reported that mortality over the first year of life was higher than had been estimated from changes in litter sizes (an inappropriate method of estimating cub mortality). Specifically, estimated mortality rates for black bear cubs were 25 to 30% and 30 to 40% for brown bear cubs. Assumptions necessary to calculate mortality rates have not held in any of the polar bear populations that have been well studied.

During the subadult stage, animals disperse from the population—an unacceptable violation of mark and recapture assumptions—hence useful estimates of subadult mortality are rare. Bunnell and Tait (1981) noted that the few data available indicated rates of subadult mortality of about 15 to 35% annually, higher than indicated by data derived from live adults.

Estimates of mortality rates of both subadult and adult bears are confused by the impacts of hunting. Cowan (1972) suggested that most of the surviving bear populations were limited by their major predator, man. In their review of the mortality rates of North American *Ursus*, Bunnell and Tait (1981) treated age structures of 30 populations, only one of which was not hunted. Estimated mortality rates of the hunted black and brown bear populations were two to three times greater than for the single unhunted brown bear population. Reproductive behavior of bears also modifies their age structure. Reproduction can become synchronized in alternate years (Free and McCaffrey 1972; Collins,

1974; Rogers, 1976; Lindzey and Meslow, 1977b). Studies cited earlier indicated that among all *Ursus*, most females may forego reproduction during a particular year. Bunnell and Tait (1981) found that the most effective approach to accommodate the resultant erratic age structures of bears was an algebraic transformation of the Chapman-Robson statistic to yield an estimate of the mean mortality rate per year.

Considering only the capture data sampling live, hunted populations, it was found that the female mortality rates were consistently lower than those for males, ranging from 9.8 to 24% /year. Weighted averages were 17.7, 16.6, and 19.4% /year for polar, black, and brown bear females, respectively. Thus, there is broad agreement with the relative rates suggested in Figure 1. On average, estimated mortality rates for males are greater than the rates for females; 21.6, 25.9, and 23.4 respectively, for polar, black, and brown bears. Much of the difference between the sexes is a function of their differential vulnerabilities to hunting, as are the differences between mortality rates derived from live and dead samples (Bunnell and Tait, 1981). Since hunting appears to represent the dominant proportion of bear mortality (whether mortality rates are derived from live or dead samples), interpretation of mortality rates is inextricably related to an understanding of the predator-prey interaction between man and bear. Models of this interaction were proposed by Bunnell and Tait (1980) and evaluated by Bunnell and Tait (1981).

POPULATION REGULATION

Background

Bears have few enemies other than man and conspecifics. The omnivorous food habits of most species frequently have been assumed to ensure an adequate food supply. Therefore, by the process of elimination, it often has been deduced that numbers must be self-limited by social factors.

We suggest that within genus *Ursus* a broad but consistent pattern to population regulation is evident. Nutritional condition dominates the reproductive rate, and social mechanisms facilitate access to, or exclusion from, sources of nutrition. Imposed on these fundamental constraints is the bear's apparent desire and ability to impose a haremlike structure on the mating system.

In presenting this suggestion, we treat reproductive rates and mortality rates separately. Furthermore, we consider that reproductive features are largely density independent, while influences of mortality are invoked at high densities (compare to pattern described in Chapter 25) largely through dispersal of subadults.

Regulation of Reproductive Rate

Age of first reproduction, litter size, and breeding interval all appear to be dominated by nutritional condition. Mean age of first reproduction within

specific bear populations is generally the age at which females attain adult weight, or slightly later. This phenomenon itself generates broad regional differences in realized natality rates. For example, females among the northern interior grizzly attain adult weights at age 6 to 8 years, and first give birth at about age 7 to 9 years (Pearson, 1975; Reynolds, 1976), while coastal populations grow more quickly and reproduce earlier (see data of Hensel et al., 1969; Glenn, 1973; Glenn et al., 1976). Similar comparisons are possible among black bear populations; for example, compare Jonkel and Cowan (1971) with Rogers (1976, 1977). The carnivorous polar bear more consistently has a rapid growth rate.

Among black and brown bears, females that do not gain sufficient weight prior to denning generally fail to produce cubs. Rogers (1976) reported that none of 16 adult female black bears weighing less than 67 kg on October 1 produced cubs, while 28 of 30 females weighing more than 80 kg and without cubs the previous season did produce cubs. It is likely that delayed implantation facilitates effective "abortion" of the pregnancy. Among polar bears, underweight females appear more often to give birth and then lose the litter (Stirling et al., 1976). Striking evidence is available among polar bears in the Canadian Arctic that experienced ice conditions unfavorable to seal populations and to polar bear hunting of seals. Comparing "before" and "during" unfavorable conditions, we note that the total population declined 33%, the percentage of females with cubs of any age declined from 82.2 to 54.7, and yearlings as a proportion of the population declined from 15 to 3.6% (data of Stirling et al., 1975, 1977b). Observed litter sizes of cubs, however, changed insignificantly, from 1.69 ± 0.05 to 1.61 ± 0.08 . During periods of low food abundance, polar bears dispersed widely, seeking more favorable hunting grounds; many females postponed breeding, yearling mortality increased, and entire litters apparently were lost.

A broader relationship is evident between mean litter size and midlatitude of the denning area (Figure 2). Harestad and Bunnell (1978) utilized latitude as a surrogate variable for productivity. These workers noted that regardless of weight or trophic proclivity, mammalian species showed larger home ranges at greater latitude, implicating lower primary productivity with increasing latitude. In all but the most northern regions, female polar bears and their young actively forage for vegetation upon emergence from the maternal den (e.g., Stirling et al., 1977a). At more southerly latitudes, the vegetation and amounts of energy plus nutrients are more abundant upon emergence than in the north. Latitude of denning and litter size show a clear statistical relationship ($r = 0.77$; p of zero slope < 0.003) for the 12 studies summarized in Figure 2:

$$L(x) = 3.05 - 0.02x \quad (1)$$

where L denotes mean litter size and x denotes latitude, degrees north ($^{\circ}$ N).

Similar broad relationships are evident among black and brown bears. In western North America, black bears typically dwell in coniferous forests, their

Figure 2 Relationship between mean litter size and midlatitude in degrees north of the denning area among polar bears.

mean litter sizes range from 1.32 to 1.96 with a mean of 1.71 (Table 2). In eastern North America, black bears more frequently inhabit deciduous or mixed forests, where berries and mast commonly provide energy and nutrient-rich forage. Mean litter sizes of black bears east of 95°W range from 2.15 to 2.74 with a mean of 2.42. Other attributes of their life histories also differ. Mean weights of adult black bears from the west (Washington, California, Montana, and Alberta) are about 93.5 kg for males and 64.5 kg for females (Table 1). Eastern black bears are about 40% larger. Growth rates are also faster in the east, and ages of first reproduction correspondingly younger: 5 to 8 years in the west, about 4 years in the east (Table 3). In eastern populations, the breeding interval is more commonly two years (Erickson, 1964; Free and McCaffrey, 1972; Rogers, 1976), while in the west it usually exceeds 3 years (Table 3).

There is also evidence of the importance of nutrition to black bear populations within a given area. Jonkel and Cowan (1971) reported that reproduction of black bear in Montana approached zero when huckleberries (*Vaccinium* spp.) were scarce. Rogers et al. (1976) noted that mean litter sizes observed near sources of garbage in Michigan ($\bar{x} = 3.1$, $n = 7$) were significantly larger ($p < 0.01$) than those observed in the same area but away from sources of garbage ($\bar{x} = 1.99$, $n = 129$) (Erickson et al., 1964). In Minnesota, captive black bears receiving rich diets developed more rapidly than did wild bears, even when captive bears were caged together with larger bears that dominated them (Rogers, 1976). Captive females produced their first cubs at 3 years of age, wild females

with ready access to garbage at 4 to 5 years ($\bar{x} = 4.4$), and those with little or no access to garbage, still later at age 4 to 7 years ($\bar{x} = 5.6$) (Rogers, 1976). Rausch (1976) reported similar findings for black bear in Alaska. Rogers (1976) further noted that "only 33% (14/43) of the females 5 years of age or older were accompanied by cubs following years of scarce food, whereas 44% (17/39) were with cubs following years of moderately abundant food, and 79% (23/29) were with cubs following years of exceptionally abundant food."

The eastern forms of the grizzly have been extirpated so potential east-west differences cannot be examined. There are, however, differences between interior forms and the coastal forms, that have access to salmon. Omitting the Yellowstone population, which until recently frequently exploited garbage dumps, the weighted mean of cub litters is 1.88 for interior populations (2.00 when Yellowstone bears are included). For coastal populations, the comparable estimate is 2.22 (Table 2). Data are sparser for age of first reproduction. Hensel et al. (1969) estimated the mean age of first reproduction for the coastal population on Kodiak Island at 4 to 5 years. The northern interior populations (Yukon and Alaska) breed much later, at 7 to 10 years, while southern interior populations are only a year or more delayed, behind coastal forms (Table 3).

The association between adult weight and reproductive rates is consistent with that observed in black bears. Adult female grizzlies of interior populations weigh about 100 to 140 kg, whereas along the coast they weigh 120 to 200 kg (Table 1). When they finally reproduce, female grizzlies of the northern interior are only slightly heavier than female black bears from eastern North America.

Together, these observations imply strong nutritional control on all reproductive parameters. Age of first reproduction lags slightly behind the age at which adult body weight is attained. Both litter size and breeding interval are correlated with health and weight of the mother.

If nutritional condition is indeed dominant in regulating populations, one might anticipate a territorial spacing mechanism. In theory, territoriality would be the optimal spacing mechanism where resources were plentiful and evenly distributed, or accessible and predictable. Conversely, it would not pay to defend areas in which food was patchy or unpredictable in abundance (Horn, 1968; Wiens, 1976). Limited overlap of home ranges has been interpreted as evidence of territoriality. Among black and brown bears, reported overlap of home ranges within sex classes has ranged from slight (Jonkel and Cowan, 1971; Poelker and Hartwell, 1973; Pearson, 1975; Rogers, 1976) to extensive (Lindzey and Meslow, 1977a; Reynolds and Beecham, 1980; Craighead, 1976; Berns et al., 1980). Available data seldom permit evaluation of the spacing mechanism relative to forage abundance. Jonkel and Cowan (1971) felt that the great diversity of topography, climate, and vegetation on their study area permitted bears to occupy small areas of limited overlap, which these investigators interpreted as territories. Presumably, the diversity provided continuously renewing food resources that were uniformly distributed. Reynolds and Beecham (1980) noted extensive overlap, which they attributed to patchy and unpredictable forage production. Where overlap of home ranges is low, it is more often lower for

females than for males, again implicating the importance of abundant forage for successful reproduction.

The erection of dominance hierarchies at concentrated food sources, such as berry patches, salmon streams, and garbage dumps (e.g., Stonorov and Stokes, 1962; Frame 1974; Rogers, 1976; Egbert and Stokes, 1976), indicates both the lability of social organization among *Ursus* and the importance of social organization in allocating food resources. Generally, it appears that access to food is not greatly restricted by social factors. Where forage is abundant, populations reproduce well. Dominance hierarchies at concentrated food sources appear to operate primarily in mediating communal access to food by an often solitary and aggressive animal. We conclude that reproductive rate is nutritionally regulated in a largely density-independent fashion.

Regulation of Mortality

Nutritional factors appear to regulate the rate at which a population can grow by controlling fecundity generally in a density-independent fashion. Upper limits to bear abundance appear to be determined by density-dependent mortality factors. Analyses by Bunnell and Tait (1981) support the suggestion of Cowan (1972) that the major cause of mortality in modern bears is hunting by man. Of the 23 studies on 30 populations reviewed by these workers, only one examined an unhunted population. Therefore, discussion of "natural" mortality unassociated with man is necessarily speculative. We noted earlier that conspecifics were the bear's next most important mortality agent after man. Here, we argue that adult males regulate population density by killing or evicting younger males (see also Chapter 5). The manner in which male aggression enhances male fitness is discussed subsequently. For the present, we note that male bears enhance their individual fitness by reducing the density of other adult males. Evidence for such density-dependent regulation is sometimes indirect, but it is plentiful and logically consistent.

Examples of conflict among adult males resulting in severe wounding or death occur in all North American *Ursus*: for polar bear, see Løng (1970); brown bears, Pearson (1975), and black bears, Beecham (1980). Although this form of conflict could serve to reduce adult male density, it represents a high degree of risk for both participants. Males are also aggressive toward younger bears. "Murder" of subadults and cubs has been observed in all species [polar bear: Nansen (1897), Parovshchikov (1964), Løng (1970); brown bear: Craighead and Craighead (1967), Pearson (1975), Egbert and Luque (1975); black bear: Erickson (1957), Jonkel and Cowan (1971), Beecham (1980)]. Subadults may simply be driven from the area, as with brown bears (Craighead and Craighead, 1967) or as with polar bears, driven from their freshly killed prey (Pedersen, 1945; Løng, 1970; Stirling, 1974; Stirling and Archibald, 1977). Furthermore, subadults frequently show greater rates of dispersal and larger home ranges than do adults (Stickley, 1961; Erickson and Petrides, 1964; Reynolds and Beecham, 1980). Jonkel and Cowan (1971) observed large losses of subadults from their

black bear population. Enforced eviction of subadults from more productive habitat could help regulate population numbers. Stokes (1970) suggested that dispersal may result from social intolerance and that social intolerance increases rapidly with density. In brief, there is direct and indirect evidence that older individuals—primarily adult males—act to reduce the survivorship or density of subadults. (The analysis by McCullough (Chapter 9) indicates that this is the case for the Yellowstone grizzly population.) Rogers (1976, 1977) documented that, in black bears, the interaction is principally between adult males and subadult males. We suggest that among Ursidae, adult males have evolved an aggressive disposition directed toward subadult males. The resulting eviction or "voluntary" evacuation from the area by subadult males results in low recruitment of adult males and a disproportionate adult sex ratio in the population. We note subsequently that such behavior, even if directed against one's own offspring, would serve to increase fitness of individual adult males.

Over evolutionary time, these subadult male vagabonds would either experience a high mortality rate or settle new areas. In recent times these subadults have become the principal victims of man as predator.

The greater apparent mortality rates of males over females indicate the greater vulnerability of males to hunting. Among black and polar bears, the generally greater apparent mortality rate of killed males over captured males indicates a biased selection in the kill toward younger over older males. Among grizzly bears, the picture is ambiguous. Data of Nagy and Russell (1978) suggest hunter selection for young males, but represent a small sample; data of Glenn (1975), Wood (1976), and Johnson (1980) suggest hunter bias for older males (Bunnell and Tait, 1981).

Together, these observations suggest that evidence of density dependence should be present in the age structures and dynamics of bear populations. Density dependence can be incorporated into a simple model used to develop the isoclines (see Figure 1). The assumption evaluated is that older individuals, primarily adult males, act to reduce the survivorship or density of subadult bears. The older bears may be either the direct source of mortality or an indirect source of reduction by driving the younger bears away. The model assumes that the rates of mortality and dispersal of male and female subadults increase with increasing numbers of males.

Simulated age structures are compared with data from an un hunted population of grizzlies in Yellowstone and a hunted population from northern Canada (Figure 3). Several features are apparent here. First, the age structure differs between the hunted and un hunted populations in the manner anticipated if density dependence was an important regulating mechanism. Second, the explicit formulation of the model closely approximates field measures. The major difference between simulation and data for the un hunted population is among the oldest age classes. The weakest assumption of the model, a high rate of mortality for old adults, was suggested by examining the data of Craighead et al. (1974). However, the review of mortality patterns by Caughley (1966) suggests that increasing mortality with age is general among mammals. The scale in

Figure 3 Simulated (dashed line) and sampled (\circ Craighead, et al., 1974; \bullet Pearson, 1975) age distributions of hunted and unhunted populations of grizzly bears. Sample age distributions have been scaled to a common basis for comparison.

Figure 3 is logarithmic, and the number of bears older than 15 years does not represent a significant segment of the population. The principal effect of hunting is to increase the mortality rate of adult animals. In both simulation and data, the slope of the curve through adult age classes steepens and the characteristic kink in age structure separating subadults from adults is removed.

Despite its simplicity and common-sense appeal, the notion of a specific form of density dependence is nontrivial and its rigorous evaluation is important (see Chapter 9). Whereas density-dependent regulation in wildlife population appears to be general (Chapter 23), it need not be resident in any specific portion of the population and, in many ungulates, it appears to be diffuse within the population. There may be value in concentrating the mechanism in the most stable portion of the population. Older male bears are subject to very few forms of mortality and thus provide an ideal regulatory mechanism. If, as field observations and simulation suggest, older males are the regulatory mechanism, there are important implications to harvest and control. Removal of the older males represents an unnatural, or at least unusual, form of mortality, and one that greatly reduces the effectiveness of intrinsic control. We know too little about bear behavior to speculate on how this removal may affect mating systems in sparse populations, but it seems clear that those populations having a higher reproductive rate (black bears) will be difficult to control by hunting, a practice that selects adult males.

Figure 4 illustrates the change in total size of a bear population simulated using the model that generated the close approximations to field data (Figure 3).

Figure 4. Simulated changes in total size of a population with density-dependent regulation from which 45 adult males and 5 adult females were removed.

The projection simulates removal of 45 adult males and five adult females from an otherwise unhunted stable population. The removal abnormally affects that segment of the population that controls total population size with resulting "overcompensation." Far more than 50 young bears "escape" into the adult segment of the population. The effect is not dampened quickly and the population does not return to its original level until after about 25 years (one generation) (Figure 4).

Data of Kemp (1972, 1976) indicate that the simulated pattern occurs in natural populations as well. Kemp experimentally removed adult male black bears from a population in Alberta. After 26 large adult males were removed from the population of about 80 animals, the population doubled. The increase in the population was attributable primarily to a demonstrated increase in numbers of subadult males, and possibly to increased subadult survivorship. The magnitude of immigration could not be evaluated. We conclude that natural mortality of bears is density dependent with control resident in older males, in basic agreement with McCullough (Chapter 9).

FITNESS

Background

The mortality factor dominating the population dynamics of bears, namely, human predation, is evolutionarily recent. The greater vulnerability of subadult and adult males in this mortality, although fortuitous, must be the consequence

of other selection pressures. Despite apparent value in regulating population density, these selection pressures should be considered within the context of individual fitness.

Our concept of fitness is that of Orians's (1969) *average reproductive success*—that is, an animal increases its fitness if it increases its genetic contribution to future generations. In a nonexpanding population with equally competitive offspring, fitness can be closely approximated by the total number of offspring produced.

Males

Male bears can improve their individual fitness simply by mating successfully with more females. The process of successful mating by the male can be considered in two phases, the search phase and the encounter phase. The search phase for black bears has been discussed by Rogers (1977). Male bears roam widely, eventually locating females, possibly by following scent trails. On the average, less than one-third of adult females will be in estrus each year (Table 3). Male bears can increase their search success by increasing their home range size to include a number of female home ranges. On the average, home ranges of males are 5.4 and 5.6 times larger than those of females for black and brown bears, respectively (Bunnell and Tait, 1981). Rogers (1977) reported that the home range of each mature male included the "territories" of 7 to 15 females. Jonkel and Cowan (1971) noted extensive overlap in home ranges between adult black bears of opposite sex, but little overlap of adult bears of the same sex. In the Yukon, Pearson (1975) observed extensive home-range overlap between male and female brown bears.

The empirical relationships between size of home range and body weight among mammals, noted by McNab (1965), have been extended by Harestad and Bunnell (1978). The home range of omnivorous mammals is proportionate to body weight to the 0.92 power. Sexual dimorphism does not appear to confer advantages by partitioning forage resources among large omnivores. We suggest that the larger body size of male Ursidae (Table 1) represents in part an adaptation that favors the establishment of larger home ranges and, thus, access to an increased number of potential mates.

The second phase of successful mating, the encounter phase, includes copulation. In its simplest form, a lone male meets and copulates with a lone female. An unusual example among brown bear is provided by Herrero and Hamer (1977). A male brown bear actively herded and confined a female to the peak of a mountain for two weeks. Copulation did not occur until the end of the confinement period. More often, however, the encounter phase is complicated by the presence or arrival of another male. Then, copulatory rights are established by contest between the males or through recognition of a dominance hierarchy. Hornocker (1962) observed that the Yellowstone grizzly established a dominance hierarchy that presumably reduced the incidence of actual fighting. Pearson (1975) observed fresh wounds on most large male grizzlies in the Yukon during

the breeding season. Large size confers selective advantage by promoting success in encounters. Encounters between male black bears "were often settled by large males simply chasing away smaller ones" (Rogers, 1977).

But it is not sufficient to achieve success in both searching and encountering an estrus female. Successful mating requires that procreation follow copulation. The promiscuous behavior of the female grizzly (Craighead et al., 1969) and black bear (Rogers, 1977), coupled with induced ovulation, leaves the resolution of successful mating indeterminate. The probability of a bear siring a cub is likely the inverse of the number of males that copulated with the mother. Litter mates need not have a common father. A male's fitness would increase hyperbolically with decreasing promiscuity of the female. Males could remain with the female after copulation and fend off other amorous males. They would then lose their own promiscuous opportunities, might not be able to fend off a large male, and might not have been first to copulate with the female. For whatever reason, it is sufficient to note that males do not generally stay with the female after copulation (Craighead et al., 1969; Herrero and Hanser, 1977 for grizzly; Rogers, 1977 for black). Thus, the adult male's reproductive fitness critically depends on, and is sensitive to, changes in the relative density of adult males to adult females. Anything an adult male does to decrease the abundance of adult males increases his own individual fitness. Thus, we find the density dependence described earlier: male aggression enhances individual fitness.

Evaluation of the presence of density dependence was discussed in association with Figures 3 and 4. We have suggested that adult males reduce numbers of subadult males to generate an adult sex ratio biased toward females. A simple test of this hypothesis would be to examine the adult sex ratio of a "natural" population. The population must be unhunted: park populations with access to garbage dumps might be inadequate tests. Dumps may provide refuges preserving subadult males through to adulthood. Among eastern black bears, males represented 80% of those at garbage dumps (Erickson et al., 1964), and 67% (Rogers et al., 1976) of those feeding at garbage dumps, campgrounds, or residential areas. Rogers et al. (1976) also noted that 72% of those males were age 3 years. McNeil Falls, with its concentrated salmon run, may not be broadly representative for similar reasons.

Females

Circumstances differ for female *Ursus*. With mate selection largely the province of males, females can devote their efforts to rearing of young. From Figure 1 it is apparent that female bears have two broad options whereby they can increase their fitness—to reproduce at an earlier age or to produce more young per unit time after becoming reproductive. The latter option involves shortening the breeding interval or increasing the litter size. All three aspects are under strong nutritional control. Studies have confirmed that territoriality or exclusiveness of home ranges is more strongly expressed in females than in males (Jonkel and Cowan, 1971; Pearson, 1975; Rogers, 1976). The optimum of territoriality is

available to females, as their smaller body size more frequently allows them to establish smaller exclusive home ranges. It is also likely that territoriality is more often expressed in the females because they have a greater, and longer-term investment, at stake. Although adult females appear to be more tolerant toward their offspring (Pearson, 1975; Rogers, 1977) female territoriality may ultimately limit female density with the resulting dispersal of subadult females.

Having established access to forage, there is relatively little a female bear can do to enhance fitness. Age of first reproduction and litter size will likely be established by the forage base and are beyond her control. All she can modify to increase her fitness is the breeding interval, and this only by abandonment of small litters to terminate lactational anestrus. Tait (1980) has documented the value of abandonment to grizzlies, which can be extended to black and polar bears as well.

Abstract. Many wildlife species are managed based on the compensatory mortality hypothesis, which predicts that harvest mortality (especially adult male mortality) will trigger density-dependent responses in reproduction, survival, and population growth caused via reduced competition for resources. We tested the compensatory mortality hypothesis on two cougar (*Puma concolor*) populations in Washington, USA (one heavily hunted and one lightly hunted). We estimated population growth, density, survival, and reproduction to determine the effects of hunting on cougar population demography based on data collected from 2002 to 2007. In the heavily hunted population, the total hunting mortality rate (mean \pm SD) was 0.24 ± 0.05 (0.35 ± 0.08 for males, 0.16 ± 0.05 for females). In the lightly hunted population, the total hunting mortality rate was 0.11 ± 0.04 (0.16 ± 0.06 for males, 0.07 ± 0.05 for females). The compensatory mortality hypothesis predicts that higher mortality will result in higher maternity, kitten survival, reproductive success, and lower natural mortality. We found no differences in rates of maternity or natural mortality between study areas, and kitten survival was lower in the heavily hunted population. We rejected the compensatory mortality hypothesis because vital rates did not compensate for hunting mortality. Heavy harvest corresponded with increased immigration, reduced kitten survival, reduced female population growth, and a younger overall age structure. Light harvest corresponded with increased emigration, higher kitten survival, increased female population growth, and an older overall age structure. Managers should not assume the existence of compensatory mortality when developing harvest prescriptions for cougars.

Key words: carnivore; compensatory mortality hypothesis; cougar; density; emigration; hunting; immigration; mortality; population growth; *Puma concolor*; source-sink; survival.

INTRODUCTION

Density-dependent population regulation has been experimentally demonstrated for a variety of animals and forms the theoretical basis for sustainable hunting of polygynous mammals (Caughley 1977, Caughley and Sinclair 1994, Ginsberg and Milner-Gulland 1994, Strickland et al. 1994). The compensatory mortality hypothesis predicts that harvest mortality, especially of adult males, triggers density-dependent responses in reproduction, offspring survival, and female population growth by reducing competition for resources (Connell 1978). In unhunted or lightly harvested populations, higher densities generate increased competition for resources, resulting in decreased reproduction, offspring survival, and female population growth. Therefore, removal of adult males in polygynous mating systems

is generally considered to have benign or beneficial effects on population growth (Errington 1945, Frank and Woodroffe 2001, Johnson et al. 2001).

The compensatory mortality model has been demonstrated for a variety of ungulates (Staines 1978, Burnham and Anderson 1984, Peek 1986, Bartmann et al. 1992, White and Bartmann 1998), but little evidence suggests that the model fits carnivore populations (Franke and Woodroffe 2001, Milner et al. 2007). Because life histories of carnivores and ungulates differ, we would also expect that density dependence might operate differently. Ungulates typically have restrictive or limited dispersal movements compared to carnivores (Chepko-Sade and Halpin 1987, Howe et al. 1991, Franke and Woodroffe 2001, Zimmerman et al. 2005, Whitman et al. 2007). Therefore hunting males is likely to reduce local herbivore densities but may not have the same effect on carnivores, which display long-distance, density-independent dispersal by males. Such intrinsic emigration can depress population density, and intrinsic immigration can increase population density regardless of birth and death rates (Franke and Woodroffe 2001, Festa-Bianchet 2003). This exchange of animals via immigration and emigration may offset expected chang-

es in density and associated effects on vital rates of resident female animals. As a result, harvest levels that are considered beneficial or benign to an ungulate population may impose additive mortality on carnivores (Franke and Woodroffe 2001, Festa-Bianchet 2003, Swenson 2003).

Cougars (*Puma concolor*) are managed for sport harvest and population control based on compensatory mortality throughout the western United States (Strickland et al. 1994, Cougar Management Guidelines Working Group 2005:71–82). Managers seeking to provide trophy-hunting opportunities often adopt strategies that seek to reduce male densities and keep female numbers high (Hemker et al. 1984, Ross and Jalkotzy 1992, Lindzey et al. 1994, Spreadbury et al. 1996, Logan and Sweanor 2001, Martorello and Beausoleil 2003). However, young male cougars often disperse long distances. Harvesting of adult males can create vacancies that attract these young dispersers to vacated territories (Hemker et al. 1984, Logan et al. 1986, Ross and Jalkotzy 1992, Logan and Sweanor 2001, Stoner et al. 2006, Robinson et al. 2008). Robinson et al. (2008) showed that heavy hunting pressure on cougars did not reduce the population in a small-scale management area because of compensatory immigration. Their results suggest that density dependence in cougar populations may act through dispersal and that models of cougar management based on the compensatory mortality hypothesis may be inappropriate.

We tested whether hunting supported the compensatory mortality hypothesis by comparing demographic parameters from two Washington State cougar populations, one heavily hunted and one lightly hunted, from 2002 to 2007. The compensatory mortality hypothesis predicts that heavy hunting of cougars will result in (1) decreased male densities, (2) increased maternity rates, (3) increased survival of young, (4) decreased natural mortality, and (5) increased female population growth; and that low levels of harvest will result in (1) increased male densities, (2) decreased maternity rates, (3) decreased survival of young, (4) higher natural mortality rates, and (5) decreased female population growth.

STUDY AREAS

We monitored cougar population in two study areas >250 km apart and managed under different hunting strategies. Heavy hunting with the aid of hounds (hunting mortality rate = 0.24) was permitted in the Northeast Washington study area and light hunting without the use of hounds (hunting mortality rate = 0.11) was permitted in the Central Washington study area.

Heavily hunted area (HH)

The 735-km² study area lies north of the town of Kettle Falls, and includes a patchwork of federal, state, and privately owned lands. The study area is bounded on the southeast and southwest by the Columbia and

Kettle Rivers. The Canadian–United States border forms the northern boundary. The area is part of a glacially subdued mountainous region (400–2130 m elevation) known as the Okanogan Highlands, and occupies the transition between the East-slope Cascades and Northern Rocky Mountain physiographic province (Bailey et al. 1994). Tree species include Douglas-fir (*Pseudotsuga menziesii*), western hemlock (*Tsuga heterophylla*), ponderosa pine (*Pinus ponderosa*), western red cedar (*Thuja plicata*), and subalpine fir (*Abies lasiocarpa*). Most of the 46-cm annual precipitation falls as snow, with an average of 136 cm falling from mid-November to mid-April annually. Mean annual temperatures range from –6°C in January to 21°C in July. White-tailed deer (*Odocoileus virginianus*) are the most abundant ungulate, but mule deer (*Odocoileus hemionus*), elk (*Cervus elaphus*), and moose (*Alces alces*) are also present. Common predator species besides cougar include coyotes (*Canis latrans*), black bears (*Ursus americanus*), and bobcats (*Lynx rufus*).

Lightly hunted area (LH)

The study area is located along the East-slope foothills of the North Cascades Mountains near the town of Cle Elum. The area covers 594 km² and includes a portion of the upper Yakima River watershed. The study area is bounded by the Cascade Mountains on the west, the Enchantment Wilderness on the north, and unforested agricultural lands of the Kittitas Valley on the south and east. Sagebrush steppe foothills (below 550 m elevation) transition upward to slopes covered with ponderosa pine (*Pinus ponderosa*) and Douglas-fir (*Pseudotsuga menziesii*). Subalpine fir (*Abies lasiocarpa*), Englemann spruce (*Picea engelmannii*), silver fir (*Abies amabilis*), and western hemlock (*Tsuga heterophylla*) dominate ridges at elevations >1550 m. Precipitation averages 56.4 cm/yr, with 160 cm of snowfall during winter. Mean annual temperature ranges from –7°C in January to 27°C in July. Elk and mule deer occur throughout the study area, and mountain goats (*Oreamnos americanus*) are present at higher elevations. Common predator species besides cougar include coyotes, black bears, and bobcats.

METHODS

Captures and monitoring

We attempted to capture and mark all cougars each year, from January 2002 through December 2007, by conducting thorough and systematic searches of each study area during winter when tracks can be detected in snow. We used hounds to track and tree cougars (Hornocker 1970). We immobilized treed cougars with a mixture of ketamine hydrochloride (200 mg/mL) and xylazine hydrochloride (20 mg/mL) at a dosage of 0.4 mL/10 kg of body mass, or with Telazol at a dosage of 6 mg/kg, using a projectile dart in the hindquarter (Ross and Jalkotzy 1992, Spreadbury et al. 1996). We determined sex and classified animals as kittens (0–12

months), juveniles (13–24 months), or adults (25+ months) based on physical measurements and gum regression measurements of the canine teeth (Laundre et al. 2000).

We fitted each animal with a mortality-sensing Very High Frequency collar (VHF; Advanced Telemetry Systems, Isanti, Minnesota, USA) or Global Positioning System (GPS; Lotek Wireless, Newmarket, Ontario, Canada and Televilt, Lindesberg, Sweden). Beginning in January 2005, we investigated den sites of collared females and captured kittens by hand. We implanted kittens <6 weeks old with PIT (Passive Integrated Transponder) tags (AVID, Norco, California, USA), and collared kittens that were >6 weeks old with expandable VHF (Telonics, Mesa, Arizona, USA; T. Ruth, *personal communication*) radio collars to accommodate growth. We handled all animals in accordance with Washington State University Animal Care (IACUC Permit #3133) and Animal Welfare Assurance Committee (AWAC Permit #A3485-01). GPS collars were programmed to collect locations at 4-hour intervals (six times/day). The data were retrieved using a remote communication unit. We recorded location coordinates of VHF-collared animals at one-week intervals from ground or aerial telemetry.

Despite attempts to systematically search and mark animals, we were not able to mark the entire population. Therefore, to establish a minimum population estimate for each study area we included demographic data from collared and uncollared cougars that were harvested by hunters, killed during depredation hunts, and killed by vehicle collisions (Stoner et al. 2006, Robinson et al. 2008). Washington Department of Fish and Wildlife recorded sex and age (determined by cementum annuli) for uncollared cougars killed by hunters or killed by special harvest permits or other causes. Because measurements of gum regression and cementum annuli yield comparable ages (Robinson et al. 2008), we included all collared and uncollared animals in a linear regression analysis to examine trends in age structure over the study period.

Survival

We used radiotelemetry to monitor survival of all radio-collared cougars and assigned cause of mortality as hunting, vehicle, or natural. Natural mortalities were confirmed with necropsies. We inferred cause of kitten mortalities by examining the carcass and proximity to other collared cougars.

We used the modified Mayfield method (Heisey and Fuller 1985) to estimate survival of animals because it provides increased precision when mortality rates are high, performs well in the case of small sample size typical of large carnivore species, and can identify cause-specific mortality rates (Winterstein et al. 2001, Murray 2006). We calculated annual survival rates for male and female kittens, juveniles, and adults from January 2002 to December 2007.

To determine intervals when survival probabilities were constant, we analyzed the statistical distribution of deaths over a 365-day period (Lambert et al. 2006). This yielded two mortality seasons: a high-mortality season (LH: 1 August to 31 December, HH: 1 October to 31 January) and a low-mortality season (LH: 1 January to 31 July, HH: 2 February to September 31). Annual survival was the product of seasonal survival rates (Heisey and Fuller 1985). We chose intervals for each period based on the median date of the deaths for each period. We used the Taylor series approximation method to compute variances of class-specific survival rates, and a one-tailed z test to determine whether survival rates in LH were higher than in HH (Micromort version 1.3; Heisey and Fuller 1985).

Maternity and fecundity

We calculated maternity as the mean number of kittens observed during inspection of maternal dens and from snow tracking, divided by the number of adult females observed that year (Case 2000:183). We calculated fecundity rates, $F = S_F \times M_{x+1}$, from the female survival rate in year x multiplied by their mean maternity rate in the following year (Ebert 1999). We used two-tailed t tests assuming unequal variance to compare maternity and fecundity rates from each area (Zar 1999).

Deterministic and stochastic growth rates

We constructed a survival/fecundity dual-sex Leslie matrix (Leslie 1945) to model closed-population growth for each area using RAMAS GIS (Akçakaya 2002). We assigned female age at first reproduction as 24 months, assumed an equal sex ratio at birth, and maximum age or age at senescence of 13 years (Robinson et al. 2008).

We calculated the deterministic growth rate (λ_D) as the dominant eigenvalue of the matrix under a stable age distribution. We calculated the stochastic growth rate (λ_S) by incorporating annual environmental variability (standard deviation of annual survival and fecundity rates) and demographic stochasticity. To estimate demographic stochasticity, we sampled the number of survivors in each sex and age class from a binomial distribution, and the number of kittens born each year from a Poisson distribution using the random number generator in RAMAS GIS (Akçakaya 2002). We sampled vital rates from a lognormal distribution to avoid truncations, which can occur if standard deviations are large due to sampling and measurement error. We projected each population for six years (five transitions), and calculated λ_S as the average geometric mean growth rate from 200 simulations, the point at which rates converged (Robinson et al. 2008).

Observed growth, immigration, and emigration

We determined observed growth rates (λ_O) from annual counts of collared and unmarked cougars. Each year we tallied the number of cougars (adults, juveniles,

and kittens) in each study area and calculated λ_O as $\lambda_x = (n_t/n_0)^{1/t}$, where λ_x is the annual finite growth rate, n_0 is the starting population, n_t is the final population, and t is the number of transitions between the start and end of the population projection (Case 2000). We used a one-tailed, one-sample t test to determine whether deterministic (λ_D) and stochastic (λ_S) growth rates were higher than the average six-year observed (λ_O) growth rate for LH, and whether λ_D and λ_S were lower than λ_O for HH (Zar 1999). We estimated net immigration/emigration rate (i/e) using the equations $i/e = \lambda_D - \lambda_O$ and $e = \lambda_S - \lambda_O$ (Peery et al. 2006). We also used observations of radio-collared cougars to document net emigration and immigration in each area from 2005 through 2007, the period during which we radio-monitored kittens (radio collars enabled us to document emigrants).

Population density

We estimated mean annual densities of cougars (number of cougars/100 km²) for each study area as the number of animals multiplied by the mean proportion of male and female locations that fell inside a mean annual 95% composite kernel home range of collared females (McLellan 1989). For unmarked cougars, we used the mean proportion of marked animals. We back-calculated the life span of each marked and unmarked cougar to the beginning of the study, its birth date (females), or immigration date (males) as described by Logan and Sweanor (2001:66), Stoner et al. (2006), and Robinson et al. (2008). We used a general linear model (GLM) to test for independent effects of study area and time on cougar density. We included study area, time, time², time × study area, and time² × study area as independent variables and then selected variables stepwise in a backward fashion, removing those that failed to be significant at the 0.10 probability level (Zar 1999).

Age structure

We calculated sex ratios (F:M) from collared cougars only to prevent bias that may result from hunters

selecting for male cougars (trophies). We determined whether ratios were different from equality with a chi-square goodness-of-fit test (Zar 1999). We compared mean age of cougars in each area with a two-sample t test and examined the trend over time in age structure with simple linear regression (Zar 1999).

Confounding factors

To account for possible differences in per capita resources affecting maternity, kitten survival, and female population growth, we compared cougar densities and female predation rates in the two study areas. We compared densities with a general linear model and tested for differences in predation rates with a two-tailed t test (Zar 1999).

RESULTS

Captures and monitoring

We captured and marked 103 cougars in the two study sites (57 in HH, 46 in LH) between January 2002 and December 2007. Hunters killed 50 unmarked cougars (nine females, 13 males in HH; 14 females, 13 males, one of unknown sex in LH), and one uncollared female in LH was killed by a vehicle collision. We observed 26 unmarked kittens (six females, two males, nine of unknown sex in HH; three females, four males, two of unknown sex in LH) traveling with collared females.

Survival and mortality

Fifty-three (35 in HH, 18 in LH) radio-collared cougars died during the study (Table 1). Hunters killed 26 cougars, 22 died from natural causes, three died in vehicle collisions, and two were killed from depredation hunts. Eight juveniles (two in HH, six in LH) emigrated and were censored at the last known date of their location. An additional nine (four in HH, five in LH) animals were censored due to shed collars or lost VHF signals. Of 42 radio-collared kittens, 18 survived to one

56	0.11 ± 0.04 (7)	0.05 ± 0.03 (3)	0.13 ± 0.04 (8)

year of age, 16 died from natural causes, and four were censored. Six of the “natural” kitten mortalities in HH (three females, two males, one unknown sex) were presumed to have been killed by male cougars, as confirmed by canine tooth punctures in the skull and close proximity of a collared male at estimated time of death.

Average annual survival rates, including all sources of mortality, for all radio-collared cougars in HH were 0.56 ± 0.05 (mean \pm SD) and 0.71 ± 0.06 in LH, but survival varied with age and sex classes (Table 2). Overall survival and survival of adults was higher in LH than in HH (overall: $Z = 1.98$, $P = 0.02$; adults: $Z = 1.75$, $P = 0.04$). Survival of adult females and survival of kittens was also higher in LH (adult females: $Z = 1.88$, $P = 0.03$; kittens: $Z = 1.49$, $P = 0.07$). We did not detect differences among other sex or age comparisons. Overall mortality rate from hunting was higher ($Z = 2.02$, $P = 0.04$) in HH (0.24 ± 0.05) than in LH (0.11 ± 0.04). We found no differences in natural mortality rates (HH = 0.18 ± 0.04 , LH = 0.13 ± 0.04 ; $Z = 0.77$, $P = 0.44$). The standard deviation of annual survival rates, including all sources of mortality for all cougars, was 0.09 in HH and

0.06 in LH. These values were used in the standard deviation matrix of RAMAS. We removed the six kittens from the analysis that were killed by male cougars in HH, recalculated survival rates, and found that kitten survival was not different ($Z = 0.96$, $P = 0.96$) in HH (0.59 ± 0.02) and LH (0.58 ± 0.02).

Maternity and fecundity

Mean litter size was 2.63 ± 0.80 ($n = 18$ litters) in HH and 2.47 ± 0.83 ($n = 15$ litters) in LH, and did not differ between study areas ($t = 2.04$, $df = 30$, $P = 0.94$). Proportions of females producing newborns (0.44 in HH and 0.51 in LH) were not different ($Z = -0.41$, $P = 0.68$), and proportions of females with dependent kittens (0.58 in HH and 0.75 in LH) were also not different ($Z = 1.15$, $P = 0.25$). Mean maternity in HH did not differ from that in LH (HH: 1.15 kittens/female/year vs. LH: 1.12 kittens/female/year; $t = 2.26$, $df = 9$, $P = 0.94$). Fecundity rates in HH and LH also did not differ (HH, 0.76 ± 0.63 ; LH, 0.97 ± 0.38 ; $t = 2.31$, $df = 8$, $P = 0.49$). The standard deviation of annual fecundity rates was 0.25 in HH and 0.27 in LH. These values were used in the standard deviation matrix of RAMAS.

Population growth

The deterministic annual female growth rate (λ_D) based on survival and fecundity models was 0.80 in HH and 1.13 in LH. The stochastic growth rate (mean $\lambda_S \pm$ SD) for HH (0.78 ± 0.19) was lower than in LH (1.10 ± 0.12 ; $t = 21.09$, $P < 0.01$). The observed growth rates (λ_O) based on the actual number of cougars in the study area were 0.91 (female $\lambda_O = 0.86$, male $\lambda_O = 1.02$) for HH and 0.98 (female $\lambda_O = 0.97$, male $\lambda_O = 0.96$) for LH, and were not different ($t = 0.86$, $P = 0.42$). Modeled growth rates were significantly higher than λ_O in LH (for λ_D , $t = 2.09$, $P = 0.05$; for λ_S , $t = 1.68$, $P = 0.09$) and lower than λ_O in HH (for λ_D , $t = 2.10$, $P = 0.07$; for λ_S , $t = 2.46$, $P = 0.05$). The HH population had net immigration rates of 0.11 ($\lambda_O - \lambda_D$) and 0.13 ($\lambda_O - \lambda_S$), and the LH population had net emigration rates of 0.12 ($\lambda_O - \lambda_S$).

TABLE 2. Radio-days and survival rates (mean \pm SD) by sex and age class for radio-collared cougars in northeast (HH, heavily hunted) and central (LH, lightly hunted) Washington State, 2002–2007.

Note: Sample size *n* is the number of mortalities, with the total number of monitored animals in parentheses.

TABLE 3. Densities and ages (mean \pm SD) for monitored cougars in northeast (HH, heavily hunted) and central (LH, lightly hunted) Washington State, 2002–2007.

Age and sex	HH area		LH area	
	Density (cougars/100 km ²)	Age (months)	Density (cougars/100 km ²)	Age (months)
Adults (>24 months)				
Female	1.35 \pm 0.12	51 \pm 7	1.07 \pm 0.38	68 \pm 13
Male	0.23 \pm 0.10	42 \pm 5	0.80 \pm 0.05	59 \pm 5
Total	1.58 \pm 0.17	48 \pm 5	1.87 \pm 0.42	61 \pm 3
All ages				
Female	2.83 \pm 0.76	33 \pm 7	2.32 \pm 0.44	40 \pm 6
Male	0.63 \pm 0.12	24 \pm 5	1.30 \pm 0.15	41 \pm 5
Total	3.46 \pm 0.69	27 \pm 4	3.62 \pm 0.58	39 \pm 4

and 0.15 ($\lambda_O - \lambda_D$). Observations of radio-collared cougars supported these trends; we documented five emigrants and three immigrants in LH, and four immigrants and zero emigrants in HH from 2005 through 2007.

Population density

The mean 95% composite range of females was 772 km² (95% CI = 316–1228) for HH and 655 km² (95% CI = 425–885) for LH. The annual proportion (mean \pm SD) of male GPS points within the composite range of females was 0.32 \pm 0.08 in HH and 0.43 \pm 0.16 in LH.

Time and time \times area explained significant variation in cougar density ($P < 0.10$). The final model included: area, time, and time \times area. Mean annual densities of all cougars were 3.46 \pm 0.69/100 km² in HH and 3.62 \pm 0.58/100 km² in LH, and were not different ($P = 0.26$) (Tables 3 and 4). Compared to LH, mean densities of males were lower in HH (0.63 \pm 0.12 vs. 1.30 \pm 0.15/100 km²; $P < 0.01$) and mean densities of females were higher (2.83 \pm 0.76 vs. 2.32 \pm 0.44; $P = 0.02$). Within HH, densities of all cougars and females declined over the study period, whereas we detected no change in male densities. In LH, we did not detect a change in density for any sex and age class (all $P > 0.05$; Table 4).

Sex and age structure

Mean age of the cougar population was 27 months (2.3 years) in HH and 38 months (3.2 years) in LH (Table 3). Most mean ages of cougars were higher in the LH than in HH for all age and sex classes (all $P < 0.05$), with one exception being mean age of females, which was actually higher in the HH ($P = 0.10$) (Table 3). Mean age of female cougars in HH increased ($P = 0.03$) over time and mean age of males decreased ($P = 0.07$). We detected no changes in age for LH ($P > 0.10$) across the study period.

Confounding factors

We detected no differences in mean maternity rates ($t = 2.26$, $df = 9$, $P = 0.94$), predation rates ($t = 0.79$, $df = 34$, $P = 0.44$), or population density ($t = 1.47$, $df = 1$, $P = 0.26$) between areas. The female predation rate in HH

was 6.68 days/kill (Cooley et al. 2008) and 7.04 days/kill in LH (K. White, *unpublished data*).

DISCUSSION

Data comparing demographics of two Washington cougar populations suggest that hunting does not act in a compensatory manner in cougar populations. The compensatory mortality hypothesis predicts that increased harvest mortality of males will reduce population density, resulting in lower competition for resources, reduced natural mortality, and increased reproduction and survival of young. The compensatory mortality hypothesis predicted that low levels of harvest will result in increased densities and rates of natural mortality, and decreased reproduction and survival.

In the heavily hunted area, female densities declined and male densities remained unchanged, whereas we

TABLE 4. Effects of study area (hunting level) and time (2002–2007) on density estimates of cougars (cougars/100 km²) using a general linear model.

observed no change in male or female densities in the lightly hunted area. We found no differences in rates of natural mortality (0.18 in the heavily hunted area and 0.13 in lightly hunted area) or maternity rates (1.15 in the heavily hunted area vs. 1.12 in lightly hunted area). Kitten survival was lower in the heavily hunted area (0.32 in the heavily hunted area and 0.58 in the lightly hunted area), with none of the kitten mortalities resulting from hunting or death of the mother. Our findings reject the compensatory mortality hypothesis because vital rates did not compensate for hunting mortality.

Resource availability could have influenced vital rates; however, both populations were at similar densities (3.46 cougars/100 km² in the heavily hunted area and 3.62 cougars/100 km² in the lightly hunted area) and female predation rates were not different, suggesting that resources were similar between areas. Densities were maintained via a net immigration into the heavily hunted area and a net emigration out of the lightly hunted area. The net emigration could indicate poorer resources; however, kitten survival and female population growth were higher there, suggesting that this is not the case. The net immigration rate in the heavily hunted area could suggest better resources, but kitten survival and female population growth were lower there, also contrary to the compensatory mortality hypothesis.

Instead of hunting influencing survival and reproduction, hunting was compensated by immigration and emigration in both cougar populations. The stochastic population model, based on the compensatory mortality hypothesis, predicted a 27% population decline, whereas we observed a 9% decline in overall numbers and no decline in the male population. The difference in growth rates resulted from immigration. The stochastic model assumed a closed population structure and did not account for immigration, whereas the observed growth rate accounted for the open nature of cougar populations by including immigration. Many of the mortalities resulting from hunting were replaced by animals immigrating from surrounding areas.

In the lightly hunted population, the stochastic model predicted a 10% increase in population growth, yet cougar numbers remained stable. The projected population increase was compensated by emigration rather than by decreased vital rates. Therefore, neither total population density nor competition among cougars appeared to be influenced by hunting, with immigration and emigration counteracting the effects predicted by the compensatory mortality hypothesis.

Long-distance dispersal is common in cougars (Sweanor et al. 2000, Logan and Sweanor 2001, Stoner et al. 2006) and can help to maintain overall numbers by replacing harvest mortalities with animals dispersing from neighboring areas (Hanski 2001). Rebound from heavy hunter harvest by immigration has been documented in cougar populations elsewhere (Ross and Jalkotzy 1992, Logan et al. 1986, Logan and Sweanor

2001, Anderson and Lindzey 2005, Stoner et al. 2006, Robinson et al. 2008). As a consequence, harvest models based on compensatory mortality hypothesis are unable to accurately predict the responses of cougar populations to hunting.

The heavily hunted population compensated for heavy harvest in overall numbers of cougars through male immigration. However, the female population declined ($\lambda_O = 0.86$). Although male cougars commonly disperse long distances, females are usually philopatric (Sweanor et al. 2000). As a result, fewer female immigrants are available to immigrate and replace those that are harvested, resulting in decreased numbers of females. Adult female survival is therefore vital for population growth and recovery from harvest (Martorello and Beausoleil 2003).

Harvesting adult males may increase incidences of infanticide by allowing immigration of new, unrelated males (Ross and Jalkotzy 1992, Whitman and Packer 1997, Murphy et al. 1999, Logan and Sweanor 2001). Lower kitten survival in the heavily hunted area may be a result of high male turnover from hunting. Male carnivores are known to kill unrelated young in order to induce estrous and gain breeding opportunities (Packer and Pusey 1983, Smith and McDougal 1991, Wielgus and Bunell 1995, Swenson et al. 1997, Logan and Sweanor 2001). Our observations suggest that six kittens of three litters in the heavily hunted area may have been killed by unrelated male cougars. When we removed those six kittens from the survival analysis, we found no difference in survival rates of kittens between areas, suggesting that infanticide may have been responsible for lower kitten survival in the heavily hunted area. High rates of immigration following heavy male harvest were also documented for brown bears *Ursus arctos* (Wielgus and Bunnell 1994) and black bears *Ursus americanus* (Sargeant and Ruff 2001). Female population growth declined because of sexually selected infanticide in brown bears (Wielgus and Bunnell 1994, Swenson et al. 1997). This may indicate that the compensatory mortality hypothesis may not be appropriate for many solitary, territorial, or quasi-territorial carnivores.

It is unlikely that age structure ever stabilizes in long-lived species such as cougars, which may bias our estimates of deterministic growth. Because this lack of variability assumes a stable age distribution, we have little confidence that differences between deterministic growth rates and observed growth rates act as predictors of actual population growth and believe that differences between stochastic growth rates and observed growth rates more accurately project growth rates. Additionally, despite intense trapping efforts conducted each winter, we may have missed some cougars that were present on the landscape during the study, resulting in biased estimates of observed growth and subsequent net immigration and emigration rates. The addition of the same number of cougars each year would increase density estimates, but would not change the observed

growth and emigration rates. A temporal bias, such as missing cougars only early in the study (most likely error), would yield an even lower true observed growth rate, whereas missing cougars only later in the study (least likely error) would yield a higher true observed growth rate. For example, a count of 10 cougars in 2002 and 11 cougars in 2003 would yield an observed growth rate of 1.10. If we missed three cougars in 2002, the true growth rate would have been 11/13, or 0.85. We have neither reason nor evidence to suspect that we missed more cougars as the study progressed, therefore any bias in our observed population growth rates is conservative.

CONSERVATION IMPLICATIONS

Harvest models that are based on the compensatory mortality hypothesis rely on the assumption that density reductions result in reduced competition for resources, thereby increasing survival and reproduction of remaining animals. However, our results suggest that dispersal movements may mitigate for mortalities resulting from hunting and negate compensation by other vital rates. These findings have two management implications. (1) Recovery from harvest relies on nearby source populations; therefore, cougar harvest should be managed at the metapopulation scale (Cougar Management Guidelines Working Group 2005:73–74). (2) Even when healthy source populations exist, prolonged harvest will cause female population declines via direct harvest of adult males and increased kitten mortality caused by immigration of potentially infanticidal males (Ross and Jalkotzy 1992, Logan and Sweanor 2001), and kitten abandonment from harvest of mothers (R. Beausoleil, *personal communication*). The compensatory mortality hypothesis may not be appropriate for modeling hunter harvest for cougars and other large carnivores that exhibit long-distance dispersal. Assumptions of closed populations are not appropriate for solitary carnivore species.

EXECUTIVE SUMMARY

During the late 1980's and the early 1990's, interpretation of New Mexico black bear (*Ursus americana*) harvest data was stymied by the realization that increasing, stable, and decreasing population trend were all plausible explanations for observed changes in harvest data. Various interest groups, favoring different interpretations of population trend, argued for liberalizing or limiting hunting regulations as justified by the data. Clearly, additional information was needed to interpret these data and to determine the status of New Mexico bear populations.

In 1991, responding to this need for more scientific information, the New Mexico State Game Commission instructed the New Mexico Department of Game and Fish (NMDGF) to conduct a black bear study with funding from the NMDGF and the Federal Aid in Wildlife Restoration program. Research was initiated in 1992 with an overall goal to study the ecology and population dynamics of black bears for developing methods and analytical tools to help estimate and predict trends in population size and structure in New Mexico, as influenced by human-caused mortality and environmental variation.

The study involved 2 related efforts: field investigations and population modeling including harvest data evaluation. The first component was an 8-year, field-based investigation of bear ecology within 2 distinct study areas situated in prime bear habitat. To specifically address the effect of hunting on population dynamics, 1 study area was closed to hunting for the majority of the study period. Primary objectives of the field study were to estimate black bear reproductive and survival rates, especially as related to mast production and human-caused mortality. Another primary objective was to validate the cementum annuli method for aging bears in New Mexico. Secondary objectives were to examine patterns of denning, home range, movements, habitat use, and population density between study areas and among sex-age categories. Combining all relevant data, the final objective was to extrapolate study area characteristics to identify suitable habitat across New Mexico using a Geographic Information System.

The second component involved analyses of existing NMDGF harvest data and development of an analytical tool for understanding bear population dynamics. Primary objectives were to determine relationships between the harvest sample and the sex-age composition of study populations, and to determine relationships among weather variables, mast production, and bear population characteristics. Using all relevant information, the final objective was to develop a population/environmental/hunt model and to integrate the model into management application.

This report chronicles results of this 8-year study, which represents the first concerted effort to understand New Mexico black bear ecology. We also

discuss applications of the existing tools and the new tools based on this research to black bear management in New Mexico.

We conducted field investigations on 2 study areas. The Northern Study Area (NSA) was located in the Sangre de Cristo Mountains of northern New Mexico. The NSA was approximately 310 km² and was comprised of private and state lands. It was adjacent to the towns of Eagle Nest and Ute Park, and about 6 km from Cimarron. The Southern Study Area (SSA) was located in the Mogollon Mountains of west-central New Mexico. The SSA was approximately 423 km² and was encompassed within the Gila National Forest. It was remote, with the closest towns of Reserve, Glenwood, and Mogollon, located 3-16 km away.

Field data were collected using capture, den investigation, and radio-telemetry techniques. We captured bears using foot snares or culvert traps and chemically immobilized most individuals. Approximate age of bears was estimated from dental characteristics and size. A vestigial premolar tooth was extracted from bears ≥ 1 year old for age determination using cementum annuli counts. We marked each bear with numbered, colored ear tags and tattooed the same number on an inner, upper lip. We placed radio-transmitters on all females, on adult males as needed to maintain a sample of about 10 individuals, and on younger bears as needed for assessing population attributes. We monitored radio-transmitted bears from fixed-wing aircraft on a 14-day schedule during the active season. We visited dens of radio-transmitted bears to ascertain their reproductive status and change or refit collars as necessary. Weights and other measurements were obtained from all bears when possible.

Between September 1992 and June 2000, we captured 300 bears (103 females, 195 males, 2 unknown sex) 517 times, and observed 339 bears in dens (178 females, 137 males, 24 unknown sex) on 680 occasions. We placed 409 radio-transmitters on 316 bears (181 females, 135 males), and obtained 5,723 radio-telemetry locations.

Reproductive data were obtained during 268 den investigations of 80 female bears 4-27 years old. The minimum observed age of first litter production was 4 years old. Mean age at production of the first litter was 5.7 years and most females (73%) produced their first litter either at age 5 or 6 years. Natality of female bears ≥ 4 years old was 0.77 cubs/female/year and percent of females with cubs was 43%. Among previously reproductive females, natality was 1.4 cubs/female/year and percent of females with cubs was 77% ($n = 112$). Litter size ranged from 1-3 cubs and mean litter size was 1.8 cubs ($n = 115$). Observed litter interval ranged from 1-3 years and mean litter interval was 1.8 years ($n = 69$). Overall cub survival rate for 148 individual cubs from 82 litters was 55%. Recruitment of females ≥ 5 years old was 0.40 yearlings/female/year and percent of females with yearlings was 27% ($n = 232$). Recruitment of

previously reproductive females was 0.53 yearlings/female/year and percent of females with yearlings was 35% ($n = 175$).

Reproductive success was evaluated on the basis of mast production by 10 surveyed species. Acorn (*Quercus* spp.) crop failure had the greatest influence on reproduction and juniper (*Juniperus* spp.) berry failure had a secondary effect. Mast failure was associated with decreased natality, cub survival, and recruitment. Neither natality nor recruitment varied following poor to good mast production, suggesting only a minimum threshold of quality food is needed for successful reproduction. Documenting annual mast production, especially the occurrence and frequency of oak failures, may be an effective index to bear reproductive success. During 1999-2000, NMDGF officers subjectively evaluated mast production statewide. Evaluations were highly correlated with our survey results, indicating subjective criteria were adequate to distinguish variation in mast production.

Observed annual survival rates for adult and subadult females were above 90%, and rates of adult and subadult males were above 80% ($n = 591$ bear-years). Most mortality of adults and subadults was human-caused, including hunter kills, depredation kills, illegal kills, and automobile kills. Observed yearling survival was variable, ranging from 75%-97% by sex and study area ($n = 72$). Among yearlings, most mortality was from natural causes, but human-caused mortality also was observed.

Among 179 bears observed on both study areas, observed den entrance dates ranged from 25 September-7 February. The majority of bears entered dens between mid October and mid November. Mean entrance date of pregnant females was 29 October, while that of all other bears was 6 November. Among 177 bears, observed den emergence dates ranged from 21 March-5 June. Adult males emerged earliest (mean date = 18 April); females with yearlings, lone females, and subadult males emerged next (mean date = 28 April); and females with cubs emerged the latest (mean date = 7 May). Comparing study areas, the schedule of denning dates was approximately 2 weeks earlier for den entrance and 2 weeks later for emergence on the NSA than the SSA.

Bear home range and movement patterns differed by sex, age class, season, and annual mast production. Male bears had significantly larger home ranges and activity radii than female bears. For both sexes, mean activity radii and percent of long-range movements increased during the mast season, when foraging for acorns and other mast dominated activity. During years of oak failure, mean activity radii were larger than during other years. Dispersal away from natal areas was observed for 4 males monitored until age 4, but none was observed for 8 females. Nuisance and depredation activity was associated with availability of human-related foods, especially garbage. Monitoring of translocated nuisance bears indicated subadult bears, particularly males, were less likely to exhibit homing behavior than adult bears.

Bear density appeared to be higher on the NSA ($17.0/100\text{km}^2$) than the SSA ($9.4/100\text{km}^2$), but the sex-age composition was very similar for the 2 study areas. Adult females constituted approximately 30% of study populations and adult males accounted for 15-19%. Annually, relative proportions of yearlings and subadult males appeared to vary the most.

Using the habitat model, we predicted suitable black bear habitat across approximately $58,939\text{ km}^2$ (14.6 million acres), of which 75% was comprised of primary cover types. Nearly 50% of the predicted suitable bear habitat was managed by the U. S. Forest Service, 33% was under private ownership, and tribal lands comprised about 10% of the area. Statewide, 17% of predicted bear habitat was within 5 km of human-populated areas. Although currently based on relatively coarse data, the model was constructed so that future, more resolved information can be easily incorporated to update model predictions.

Extrapolating observed density estimates to areas of primary habitat yielded a statewide population estimate of 5,947 bears ≥ 1 year old. This estimate was similar to the independent estimate of 5,200 derived from population modeling for the state (excluding the Zuni, Mt. Taylor, Sandia/Manzano, and Chuska regions). These estimates refute the previous estimate of 3,000 bears used by the NMDGF, however they do not suggest a doubling of the bear population in the past decade. Rather, these estimates are based on better information and, as such, are more reliable.

Analyses of harvest data from 1985-1999 indicated bear hunters in New Mexico consistently harvested more males than females. The female proportion of annual statewide harvest ranged from 29 to 46%. Total annual bear kill by hunters was affected by many factors including season timing, hunter effort, hunter method, and mast production, as well as underlying population composition. Hunters aided with dogs had higher success rates and harvested 4 times as many female bears per hunter as those not using dogs. Later fall seasons were associated with lower total harvest and lower proportions of females in the harvest, compared to earlier fall seasons and spring seasons. Failures in oak production were associated with increases in hunter effort, hunter success, and the proportion of females in the kill.

Accuracy and consistency of the cementum annuli aging technique appeared adequate for assessing the age composition of annual hunter-killed bears and reporting of sex appeared to be accurate. However, analyses indicated harvest data were incomplete, underestimating the annual bear kill by as much as 7%.

The bear population model was designed to simulate a black bear population through time, with biological realism, hunting, and environmental influences. Using observed reproductive and survival rates, modeling indicated study populations were either stable or slightly increasing. Future utility of the

model will depend on continued input of data in the form of annual harvest records and annual surveys of mast production. Use of the model will allow for interpretation of recent demographic trends in New Mexico bear populations, a timely indication of potential overharvest, and predictive scenarios useful for selecting from several management options.

The outcomes of this research will significantly improve understanding of black bear ecology and management in New Mexico. Using the new tools provided by this study, as well as the existing tools, managers can evaluate the results and consequences of numerous management alternatives and assess past, current, and future trends in bear populations. The existing tools consist of hunter-kill records and the hunter mail-in survey. The validity of those tools has been verified to supply useful input to hunt regulation assessment and regional management decisions. The new tools include the bear population model, the model to predict suitable bear habitat, a simple annual mast survey, and the research report as a compilation and archive of these tools.

PREFACE

In the early part of the 20th century, the science of wildlife management was in its infancy, but public and government interest in this discipline intensified as the need for protection of wildlife species became apparent. Across North America, unregulated hunting had reduced or eliminated wildlife populations once plentiful. In 1914, the last passenger pigeon died, bringing the extinction of a species, once so numerous as to blacken the skies with their multitudes. In the Southwest, Merriam's elk were eradicated, and several carnivore species, including black bears, grizzly bears, cougars, and Mexican wolves, were facing unprecedented mortality from predator control programs.

Amidst these extraordinary events, New Mexico joined only a handful of other states in granting game status to black bears and grizzly bears in 1927. Conservation measures came too late for grizzly bears, but black bear populations rebounded. Today, evidence indicates black bears inhabit the same range in New Mexico as they did prior to European settlement. They tread the same mountains, consume the same foods, and possibly slumber in the very dens used by their ancestors for thousands of years.

How did these historic events come about? The answer is as relevant today as it was in 1927. The decision to protect bear populations, by setting legal hunting regulations, arose from participation of the public, the legislature, and the New Mexico Department of Game and Fish. Without involvement from each of these 3 entities, conservation of black bears might also have come too late. With this in mind, it seems fitting that the black bear was selected as the symbol of the Department of Game and Fish. Black bears may well have been the first wildlife management success story in New Mexico.

As human populations increase in the 21st century, management of black bears will only become more challenging. Creative solutions to bear-human conflict will be necessary, as well as sensible management strategies for hunting and habitat quality. But with continued public involvement and sound management based on science, existence of black bears in New Mexico can continue to be a success story for generations to come.

ACKNOWLEDGMENTS

An extensive array of people assisted and facilitated completion of this research, primarily from New Mexico Department of Game and Fish (NMDGF), Hornocker Wildlife Institute (HWI), New Mexico Cooperative Fish and Wildlife Research Unit (NMDFWRU), New Mexico State University (NMSU), and U.S. Fish and Wildlife Service (USFWS). There are many individuals whose role in helping with this research may not be recalled or even known to us. To those, we offer a collective thank you and expression of appreciation.

Several people were instrumental in the inception of this project, especially James Koch and David Salman from the New Mexico Game and Fish Commission; William Montoya and Wain Evans from the NMDGF; and Maurice Hornocker from HWI.

We acknowledge support from the NMDGF for many aspects of the study. Walter Haussamen, Chuck Hayes, and William Dunn provided administrative supervision of the project and reviews of report drafts. Santiago Gonzales, Joanna Lackey, Dan Sutcliffe, Kerry Mower, and Darrel Weybright assisted with logistics and administrative support. We owe special gratitude to Larry Temple, Nick Smith, Joel Pafford, and Bobby Griego who provided extensive assistance in the field. We thank all of the NMDGF officers that participated in the mast surveys during 1999 and 2000, and those who assisted with den work during 1999. We also recognize the support of past and present New Mexico State Game Commission members.

We thank Laurel Kagan Wiley and Penny Bartnicki from USFWS who provided Federal Aid project review and oversight.

We thank the Colorado Division of Wildlife for their loan of the modified culvert traps and other assistance. Special thanks go to Tom Beck and Lyle Willmart for their assistance.

We acknowledge the cooperation of the United States Forest Service, especially John Baldwin, Mike Gardner, Teresa Beale, and Marianne Scharn.

We thank members of the research team for their dedicated work in the field, including Kathi Clark, Mark Haroldson, Carrie Hunt, Jamie Jonkel, Margaret Kirkemide, Deborah Perkins, and Scott Tomson. We also thank Jeff Augustine, Teresa Beale, George Hobbs, Nicole Jimenez, Glenn Lorton, Steve Ringold, Ron Thompson, and Johnny Zapata for their contributions to the fieldwork.

We gratefully acknowledge the skill of our pilots, including Bob Ackroyd from Ackroyd's Surveys and Aerial Photography; Larry Himes from Grimes Aviation; the late Rick Poe from Eagle Tail Aviation; Clayton Stansell from Aviation Adventure Company; and Dick Woodsum from Star Aviation.

We thank the veterinarians consulted throughout the project including Dr. Timothy Johnson, Dr. Ulysses McElyea, Dr. Kathy Quigley, and Dr. John Wenzel.

We are grateful to the many private landowners who gave us access to their properties. Special thanks go to Bob Ricklefs from Philmont Scout Ranch; Johnny and Shirley Atmore from Atmore Ranch (now Express Ranch); Bob Allen from Ute Creek Ranch; David Vackar and Jim Baker from Vermejo Park Ranch; Phillip Mutz and the late Irene Mutz from Mutz Ranch; and Gretchen Sammis and Ruby Gobble from Chase Ranch. We also appreciate the support of the communities and businesses of Eagle Nest, Ute Park, and Reserve, New Mexico.

We thank our support staff from HWI, especially Molly Parrish. We thank Connie Alsworth, Ken Boykin, and Andrea DeLorenzo of NMCFWRU and NMSU who assisted report compilation and formatting.

Population modeling work was done under subcontract from N. Scott Urquhart, Ph.D., Statistical Data Analyst.

Permits to capture bears and use immobilizing chemicals were obtained from NMDGF or bears were captured in cooperation with NMDGF personnel. Further permits for use of controlled substances for immobilizing bears were obtained from New Mexico Board of Pharmacy and U.S. Drug Enforcement Agency. Fieldwork during 1999-2000 was approved under the NMSU Institutional Animal Care and Use Committee.

Financial and technical support for this investigation and associated publication costs was provided by NMDGF under Wildlife Restoration Grant W-131-R, Black Bear Research.

Use of brand or trade names throughout this report acknowledges the product's application to our research but does not constitute agency or cooperator endorsement of those products.

Photo credits for the cover are: Cecily Costello for Gambel oak acorns, F506 yearling in tree, F536 in den, and Baldy Meadows in fall; Robert Inman for Southern Study Area (Gila) ridges from airplane, and Gerry Lamarre for black bear on rock.

CHAPTER 1

INTRODUCTION

RATIONALE FOR STUDY

The black bear (*Ursus americanus*) is an important species in New Mexico, valued both as a big game animal and an embodiment of the southwestern wilderness. Throughout history, bears have been both revered and scorned by humankind. Management of this species must balance the positive aspects of bear-human interactions, including wildlife viewing and hunting, with negative aspects, such as nuisance problems, crop and livestock depredation, and bear-inflicted human injuries. With expanding human populations, management of these bear-human interactions will only become more challenging.

The New Mexico Department of Game and Fish (NMDGF) is responsible for managing the wildlife and fish populations of New Mexico, including black bears. Their mission is to "provide and maintain an adequate supply of wildlife and fish within the state of New Mexico by utilizing a flexible management system that provides for their protection, propagation, regulation, and conservation; and for their use as a public recreation and food supply." The NMDGF primarily manages bear populations through hunting regulations and resolution of nuisance and depredation problems.

Wildlife management is essentially governed by knowledge of the status and trend of populations. However, monitoring black bear population status is a difficult job. The solitary nature of bears, coupled with the dense habitats they generally use, prevent use of survey methods commonly used for other big game species such as elk (*Cervus elaphus*), mule deer (*Odocoileus hemionus*), or pronghorn antelope (*Antilocapra americana*). As in many states, the primary foundation for black bear management in New Mexico is information obtained from hunter-killed bears. Since 1978, the NMDGF has collected annual records of harvested bears through a mandatory reporting program. Beginning in 1985, utility of these data was improved with the requirement of proof of sex and collection of a premolar tooth for aging with the cementum annuli method. Since 1986, the NMDGF also has conducted hunter surveys to obtain data on hunter effort and methods to be used in conjunction with harvest records.

Managers often make inferences about status and trend of populations based on the sex and age composition of harvested bears. However, harvest data are not necessarily representative of actual bear populations because of differences in vulnerability and hunter selectivity between sex and age groups (Miller 1990, Garshelis 1991). One common circumstance, subject to misinterpretation, is an observed increase in the percentage of young bears in

the harvest sample. Is this increase due to previous overharvest of mature individuals or an increase in reproductive success?

During the late 1980's and the early 1990's, interpretation of New Mexico black bear harvest data was stymied by these very circumstances. Increasing, stable, and decreasing population trend were all plausible explanations for the observed changes in the harvest data. The lack of conclusive evidence for any trend did little to alleviate the growing controversy over future hunting regulations. Many guides, outfitters, and hunters favored the interpretation of an increasing trend, arguing that hunting regulations could be less restrictive. But other hunters and environmental groups defended the interpretation of a declining trend, and advocated more conservative hunting regulations. Clearly, additional information was necessary to interpret these data and to determine the true status and trend of New Mexico bear populations.

In 1991, responding to this need for more scientific information, members of the New Mexico State Game Commission instructed the NMDGF to conduct a black bear study. With funding from the NMDGF and the Federal Aid in Wildlife Restoration program (U. S. Fish and Wildlife Service) research was initiated in 1992. This 8-year study involved the NMDGF and three contracting organizations: Hornocker Wildlife Institute (HWI), Ecosystem Modeling (EM), and the New Mexico Cooperative Fish and Wildlife Research Unit (NMCFWRU) at New Mexico State University. The overall goal was to study the ecology and population dynamics of black bears for developing methods and analytic tools to help estimate and predict trends in population size and structure in New Mexico, as influenced by human-caused mortality and environmental variation.

STUDY OBJECTIVES

The study involved 2 related efforts. The first job was an 8-year, field-based investigation of bear ecology. Research was conducted within 2 distinct study areas situated in prime bear habitat. To specifically address the effect of hunting on population dynamics, 1 study area was closed to hunting for the majority of the study period. Research involved use of radio-telemetry transmitters on free-ranging bears, and although our primary objectives were related to population characteristics, use of telemetry permitted investigation of other ecological questions. Objectives of the field study were:

1. To document black bear population characteristics and dynamics, focusing on natality; cub survival; yearling survival; and adult/subadult survival relative to human-caused mortality.
2. To document black bear foraging habits and identify key foods, especially mast-producing species.

3. To quantify annual variation in production of important mast species for evaluation of its influence on reproductive success and survival.
4. To validate the premolar cementum annuli aging technique for New Mexico bears.
5. To document den entrance and emergence dates for comparison among sex/age categories and between study areas.
6. To investigate den site selection and use of elevation and habitat by denning bears.
7. To document home range characteristics, seasonal patterns of movement, subadult dispersal, and general habitat use.
8. To determine density and sex-age composition of study populations annually and with all years combined.
9. To extrapolate study area habitat characteristics to identify suitable bear habitat across the state using a Geographic Information System (GIS).

A second job involved analyses of NMDGF harvest and hunter survey data and development of a black bear population model using data collected during the field study. Primary objectives were:

1. To determine relationships between the harvest sample and the sex-age composition of study populations.
2. To determine relationships among weather variables, mast production, and bear population characteristics.
3. To develop a population/environmental/hunt model based on existing knowledge, and refined by rates observed in the field study.
4. To integrate the model into management application.

This report chronicles the results of this 8-year study, which represents the first concerted effort to understand New Mexico black bear ecology. Prior to 1992, only 2 research efforts had been conducted on New Mexico black bears. With funding from the NMDGF, Zager and Beecham (1982) conducted a preliminary investigation of food habits and habitat ecology in north-central, west-central, and southeast New Mexico. In 1988, a radio-telemetry study was initiated by a NMDGF District Officer to investigate bear-human conflicts, particularly on Philmont Scout Ranch (Jones 1991). That investigation acted as a springboard for establishment of the Northern Study Area for this study.

Further, this study and the resulting report supplements NMDGF data on hunter-killed black bears with information on vital rates, relationships with annual environmental variation, live population structure, and habitat use. The population model will provide managers with a tool for integrating harvest data with biological and environmental information to make inferences about bear population status consistent with all available information. Although uncertainty about black bear population resources will remain a challenge to bear management, the knowledge available to managers has been significantly improved.

CHAPTER 2

LIFE HISTORY AND MANAGEMENT HISTORY IN NEW MEXICO

This chapter describes the general ecology of black bears. It provides background for understanding the design, implementation, outcomes, and interpretations of this research.

TAXONOMY

Bears are members of the Family Ursidae, in the Order Carnivora, in the Class Mammalia. Other families found within the Carnivora include the Canidae (dogs), Felidae (cats), Mustelidae (weasels), and Procyonidae (raccoons). The Ursidae family is of recent origin, believed to have diverged from the Canidae approximately 20-25 million years ago (McLellan and Reiner 1994). Black bears are 1 of 8 ursid species worldwide.

At least 2 million years ago, after radiating to North America from Asia, a small forest-adapted ancestor (probably *Ursus abstrusus*) gave rise to the modern American black bear (Stirling and Derocher 1989). Despite climatic changes and competition with various species, the black bear adapted to survive to the present day virtually unchanged from 1 million years ago (Stirling and Derocher 1989). Within their evolutionary history, black bears have coexisted with several other ursid species, including the extinct short-faced bear (*Arctodus simus*) and the extinct North American spectacled bear (*Tremarctos floridanus*). The brown bear (*Ursus arctos*), which coexists with black bears in northwestern regions today, radiated into North America only about 100,000 years ago, and probably reached the Southwest about 13,000 years ago. Since then, black and grizzly bears inhabited New Mexico and probably shared similar distributions. However, grizzly bears were extirpated from New Mexico by the late 1930's.

DISTRIBUTION AND STATUS

Throughout their evolutionary history, the distribution of black bears has been basically defined by the extent of forested habitat in North America. Black bears have inhabited eastern deciduous forests from Florida to Maine, boreal forests from Newfoundland to Alaska, and montane forests from Alberta to Mexico. Fossil evidence indicates black bears were never commonly found in open habitats, such as the Great Plains, the Great Basin, or the arctic tundra, possibly due to competition with larger ursids, such as short-faced bears and brown bears (Stirling and Derocher 1989).

During modern times, black bear distribution has been most affected by deforestation, unlimited hunting, and use of poisons following European settlement of North America. Beginning in the 19th century, black bears were eliminated or greatly reduced in several U.S. states, including Illinois, Ohio,

Kentucky, Florida, Alabama, Louisiana, Arkansas, Missouri, and Texas (Servheen 1989). However, during the last century, reforestation, legal limits on hunting, and restrictions on the use of poisons have allowed population recovery in many regions. The bear population in Arkansas, and subsequently Missouri and Louisiana, also were augmented with bears transplanted from Minnesota in the 1950's. Today, black bear distribution is expanding and is known to include 32 U.S. states, 11 Canadian provinces or territories, and 6 Mexican states (Servheen 1989, Carrera 1993). Throughout their current distribution, bears are variously protected by game, threatened, or endangered status.

In New Mexico, evidence indicates black bear populations were greatly reduced by the early 1900's due to unlimited hunting and use of poisons (NMDGF 1926, Bailey 1932, Brown 1985). Much of the mortality was the result of government sponsored anti-predator programs, aimed at eliminating loss of livestock to grizzly bears, black bear, wolves, and other carnivores (Brown 1985). In 1924, the U. S. Forest Service (USFS) estimated only 1,500 black bears inhabiting the national forests of New Mexico, Arizona, southern Colorado, and southern Utah, combined (Brown 1985). In 1925, the New Mexico population estimate was 660 black bears (NMDGF 1926). Responding to public and legislative support for protection of bears, the NMDGF classified the black bear as a big game species in 1927, and set a bag limit of 1 bear/season (10-31 October). Black bear, deer (*Odocoileus* spp.), and turkey (*Meleagris gallopavo*) were included in a single big game license and this regulation remained until 1981. This protection had significant results, and the bear population appeared to rebound by the 1940's. In 1941, more than 3,500 bears were estimated to reside in the national forests of the southwest (Brown 1985). By 1967, the black bear population in New Mexico was estimated at 3,000 and stable (Lee 1967). In 1971, a regulation was adopted prohibiting the harvest of young less than 1 year of age or females accompanied by young. In 1978, a mandatory hide-tagging program was instituted and 2 further requirements were added in 1985: proof of sex and collection of premolar teeth for cementum aging. In 1982, facilitated by the separate black bear hunting license, the NMDGF initiated a survey of randomly selected license holders.

Since the first bear hunting seasons were set in 1927, timing and duration of seasons have varied. By the late 1970's, bear seasons encompassed 7-8 months each year, including parts of April, May, June, August, September, October, November, December, and January. In 1992, due to concerns about potential overharvest, NMDGF eliminated the spring bear season and reduced the fall season to 1 September-31 October. The fall season was again changed to 15 October-15 December in 1998 and 1 October-15 December in 1999.

Current distribution of black bears in New Mexico is associated with the forested mountain ranges. Bears inhabit areas ranging from the low elevation pinyon-juniper woodland and oak scrub habitats to the high elevation mixed conifer and spruce-fir forests (See Chapter 11).

LIFE HISTORY

Although taxonomically carnivores, black bears are, in fact, omnivorous. Throughout North America, diets of black bears are dominated by plant matter (Hatler 1972, Beeman and Pelton 1980, Graber and White 1983, MacHutcheon 1989, Raine and Kansas 1990). Diets of black bears in New Mexico also are dominated by plant material (see Chapter 5).

To an herbivorous black bear incapable of digesting cellulose, winter represents a time of food shortage, especially in northern regions. It is believed bear hibernation evolved primarily as a response to this seasonal scarcity of food (Pelton 1982). In most regions of North America, hibernation is a central component of the annual cycle of black bear activity, and the timing and duration of all other activities might be viewed as evolutionary consequences of this unique process. Although different from hibernation among smaller mammals, the physiological state attained by bears is generally considered true hibernation (Folk et al. 1976, Hellgren 1998), and some argue it is the most refined response to starvation of any mammal (Nelson 1980). For periods up to 7 months, a hibernating bear does not eat, drink, defecate, or urinate (Folk et al. 1976, Nelson 1980, Hellgren 1998). In all hibernators, metabolic activity is generated from energy stored in the form of fat, but small hibernators must arouse periodically to feed. Bears are capable of recycling the waste products of fat metabolism into lean body mass, while other hibernators must arouse and eliminate wastes through urination or suffer toxemia (Nelson et al. 1973, Hellgren 1980). Bears, like other hibernators, achieve energy savings by reducing their heart rate from 40-50 beats per minute (bpm) to 8-10 bpm, and lowering their metabolic rate by 27-50% (Hellgren 1998). However, concurrent with these other declines, black bear body temperature drops from 37-38°C to only 31-35°C compared to temperatures less than 10°C in other hibernators (Hellgren 1998). Bears can achieve energy savings equal to small hibernators without dramatic changes in body temperature, because of their lower surface-area to volume ratio. This maintenance of near normal body temperature also allows bears to arouse quickly in response to disturbance.

Female black bears give birth in winter dens, and in addition to their own metabolic requirements must fulfill the energetic demands of gestation and lactation during the hibernating phase. Timing of breeding season may be tied to hibernation. Although mating occurs during spring or summer, fetal development does not begin until late fall, due to the process of delayed implantation. Following fertilization, eggs divide until the blastocyst stage (about 300 cells) and remain within the fallopian tubes for several months. In late fall, the blastocyst migrates down the fallopian tubes and implants in the uterine wall, at which time gestation begins (Wimsatt 1963). Actual gestation length is approximately 30-90 days and cubs generally are born during late January or early February (Alt 1983, Hellgren et al. 1991). Black bear litter sizes are known to range from 1-5, but litter sizes observed during this study ranged only from 1-3 (see Chapter 6).

Delayed implantation may be adaptive in bears for 2 primary reasons. First, it allows breeding to occur early in the active season when it would not interfere with the prolonged fall foraging necessary to build up fat stores for hibernation. Secondly, even after mating occurs, it is postulated that delayed implantation may allow females, with fat stores insufficient for gestation and lactation, to forego reproduction by not implanting the blastocyst. No hard evidence of this process had been found, however lack of litter production has been linked to poor nutritional status (Kolenosky 1990, Noyce and Garshelis 1994, Samson and Huot 1995).

Like most other members of the Carnivora, black bears can be classified as k-selected species, characterized by slow maturation, low reproductive potential, and long life spans (Caughley 1977). Throughout North America, female black bears reach reproductive maturity and mate at ages ranging from 1-5 years, with most over 3 years. In New Mexico, the youngest females observed in estrus were 3 years old, and the youngest females observed to give birth were 4 years old (see Chapter 6).

Breeding season typically ranges from May to September with peaks in June or July. Evidence from New Mexico indicates the peak of breeding occurs in June. Prolonged dependence of offspring on their mother sets the minimum successful birth interval at 2 years. Bears have been observed to give birth in the presence of yearlings (Alt 1981) and to give birth to newborn cubs after fall separation from the previous year's cubs (LeCount 1983). Nonetheless, these events appear to be extremely rare, and we found no evidence of their occurrence in New Mexico.

Cubs remain with their mothers for approximately 16-18 months, denning with them during their second winter. Following den emergence in the spring, yearling bears generally become independent between May and July, at which time the female is usually receptive to mating. Despite independence, occasional socialization between mothers and offspring probably occurs for several months to years. Numerous studies, including this one, have documented temporary reuniting of mothers and offspring. Bear species exhibit a high degree of female philopatry. Subadult female bears often remain in the vicinity of their mother's home range and establish their own home range adjacent to their mother. Conversely, most male offspring disperse away from natal areas at ages ranging from 1-3 years old. Findings of this study concur with these general trends (see Chapter 9).

Natural life expectancy of black bears probably varies regionally, but bears living in excess of 20 years are common. During this study, the oldest female bear age documented using cementum annuli counts was 27 years and the oldest male was 23 years. The highest age recorded for litter production was 22 years and was observed for 2 bears.

CHAPTER 3

STUDY AREAS

Research was conducted on 2 study areas in New Mexico. The Northern Study Area (NSA) was located in the Sangre de Cristo Mountains of northern New Mexico (Figure 3-1). The study area was approximately 310 km² and was bounded by U.S. Highway 64 to the south and Moreno Valley to the west. The area encompassed private and state lands, including Philmont Scout Ranch, the Colin Neblett State Wildlife Area (CNWA) and the Elliot Barker State Wildlife Area (EBWA), Cimarron Canyon State Park, and several private ranches. It was adjacent to the towns of Eagle Nest and Ute Park, and about 6 km from Cimarron. It was bordered by a 2-lane highway, which received fairly high use year-round. It also enclosed numerous gravel roads, dirt roads, and trails. During the study period, recreation and cattle ranching were the primary land uses. Philmont Scout Ranch hosted up to 20,000 scouts during 3 months each summer. Access to private lands was limited and vehicular access to the CNWA was restricted to the highway.

In addition to presence of highways and towns, the primary human influences on the landscape included excavation, logging, and construction of dirt tanks. Scattered mines and dredge tailings remained from gold and copper mining activities that lasted from the late 19th to the mid 20th century. Most forests within the study area were second-growth, following selective logging, clearing for pasture, and forest fires. During the 1960's, an elaborate network of dirt roads was constructed on the CNWA to provide access for selective logging. Public driving access to the roads was restricted, allowing most roads to become overgrown. Occasional man-made dirt tanks were scattered within the area, primarily on private lands.

Topography and vegetation were diverse. Elevations range from 2,073 m (6,800 ft) on the east side of the study area to 3,793 m (12,441 ft) on Baldy Mountain. At the lower elevations, dominant habitat types included pinyon-juniper (*Pinus edulis-Juniperus* spp.) woodlands, and oak-mountain mahogany (*Quercus* spp.-*Cercocarpus* spp.) scrub. Middle elevations were dominated by ponderosa pine (*Pinus ponderosa*), mixed conifer (*Pseudotsuga menziesii-Abies concolor*), and aspen (*Populus tremuloides*) forests. Meadows of fescue (*Festuca* spp.), mountain muhly (*Muhlenbergia Montana*), grama (*Bouteloua* spp.), and bluegrass (*Poa* spp.) existed throughout the wooded habitats at lower and mid elevations. Spruce-fir (*Picea engelmannii-Abies lasiocarpa*), and bristlecone pine-limber pine (*Pinus aristata-Pinus flexilis*) forests dominated the higher elevations. An alpine tundra community, consisting of sedge (*Carex* spp.), alpine avens (*Geum rossii*), mountain current (*Ribes montigenum*), shrubby cinquefoil (*Potentilla fruticosa*), and grounself (*Senecio* spp.) surrounded the scree and talus slopes at the highest elevations. Further description of these vegetation communities is provided by Dick-Peddie (1993).

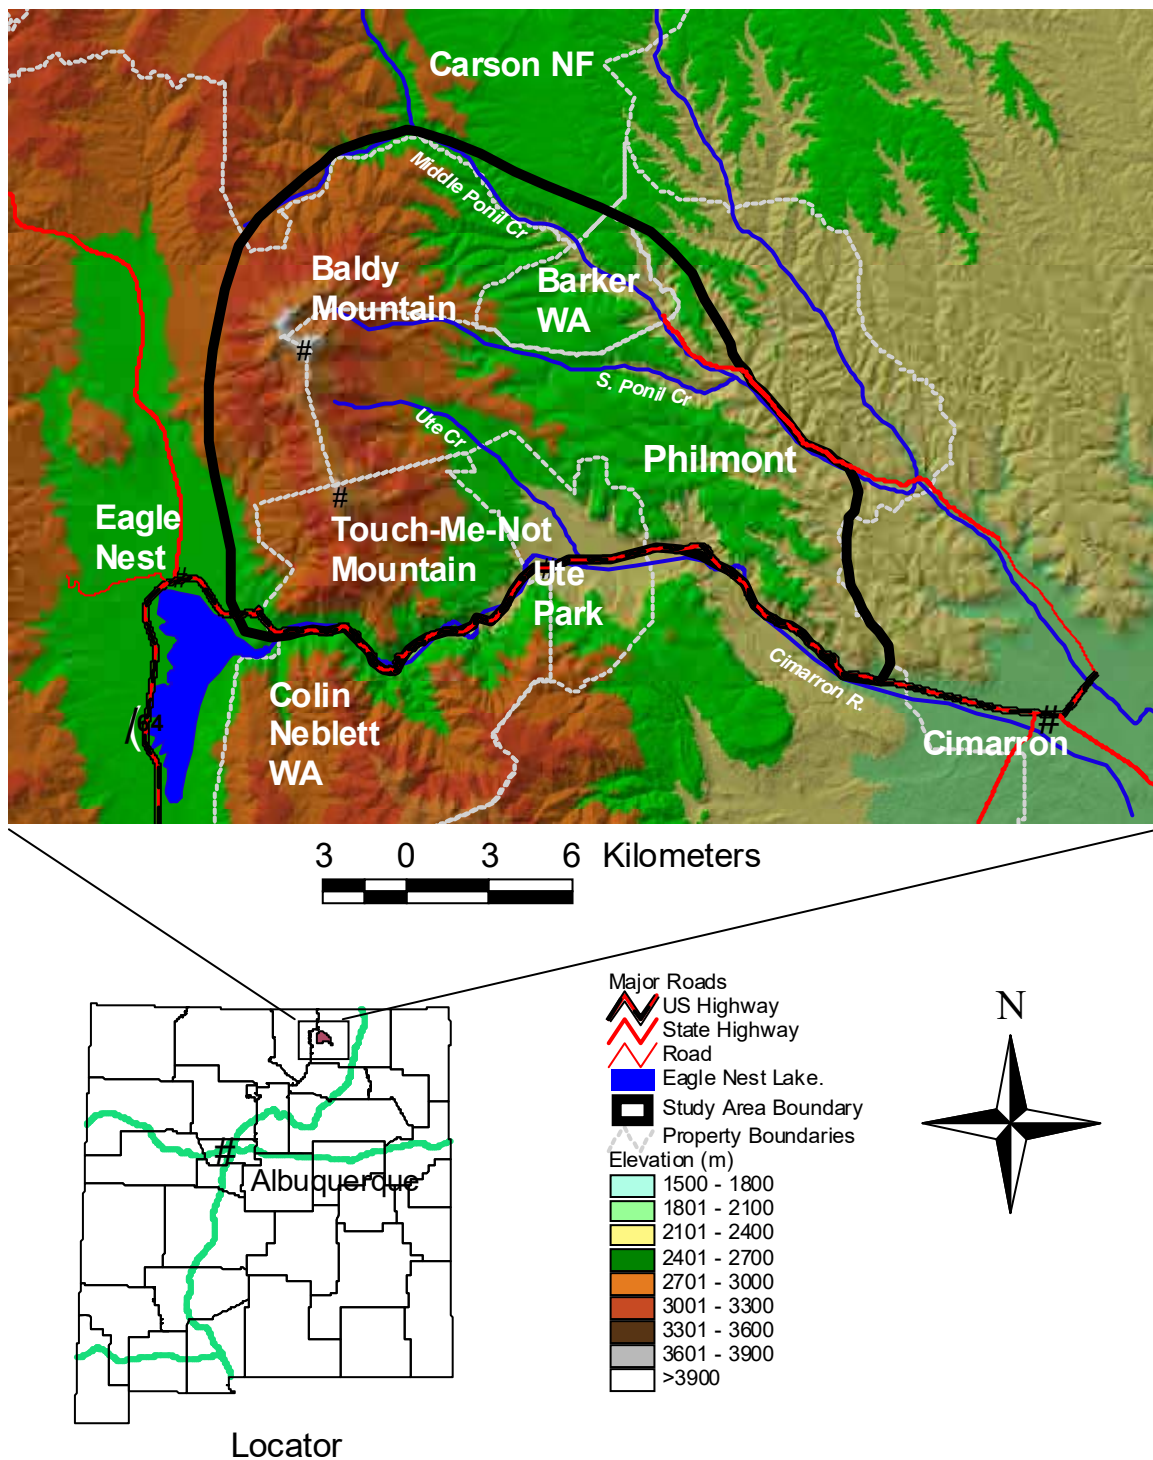

Figure 3-1. Location of the Northern Study Area of the Black Bear Study in New Mexico showing relationship to major roads, towns, and terrain.

The area included numerous permanent streams draining into the Cimarron River, including Willow Creek, California Creek, Ute Creek, Dean Creek, and Ponil Creek. Most of the smaller streams draining into these larger streams also were permanent.

Climate varied by elevation within the study area (Table 3-1). Mean January temperatures were at or below freezing and snowfall was high in the upper elevations. July temperatures were generally mild with most rainfall occurring during July-August.

Table 3-1. Climate variables recorded at weather stations close to the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1939-2000.

Parameter	NSA		SSA	
	Eagle Nest (2506 m ^a)	Cimarron (1939 m)	Beaverhead (2023 m)	Glenwood (1432 m)
Mean Jan temperature (°C)	-7	0	-1	5
Mean Jul temperature (°C)	16	21	19	24
Frost -free season (days)	70-120	145-190	110-155	180-230
Annual precipitation (cm)	37.8	41.4	37.6	40.4
Monthly snowfall Dec-Mar (cm)	25.4	15.0	10.5	4.0
Monthly rainfall Jul-Aug (cm)	6.9	7.0	6.6	6.8

^a Elevation of weather station

The area was located in Game Management Unit (GMU) 55. Prior to the study, bear hunting intensity varied within the study area. The CNWA and EBWA were closed to bear hunting since the late 1980's. Levels of bear hunting varied on private land, but were probably moderate to high throughout the area. With cooperation of private landowners, the area was closed to bear hunting so population dynamics could be studied in the absence of hunting. This closure was in effect from 1992 until 1998 when hunting was reestablished on some private land within the study area.

The Southern Study Area (SSA) was located in the Mogollon Mountains of west-central New Mexico (Figure 3-2). The area was approximately 423 km² and was bounded by U. S. Forest Service Road 141 to the north and Mineral Creek to the south. The area was encompassed within the Gila National Forest (Reserve Ranger District), but included some private parcels. It was remote, with the closest towns of Reserve, Glenwood, and Mogollon, located 3-16 km away. A 2-lane, partially paved loop road provided the main access into the study area. Numerous gravel roads, dirt roads, and trails were found on the study area, and access was usually unrestricted.

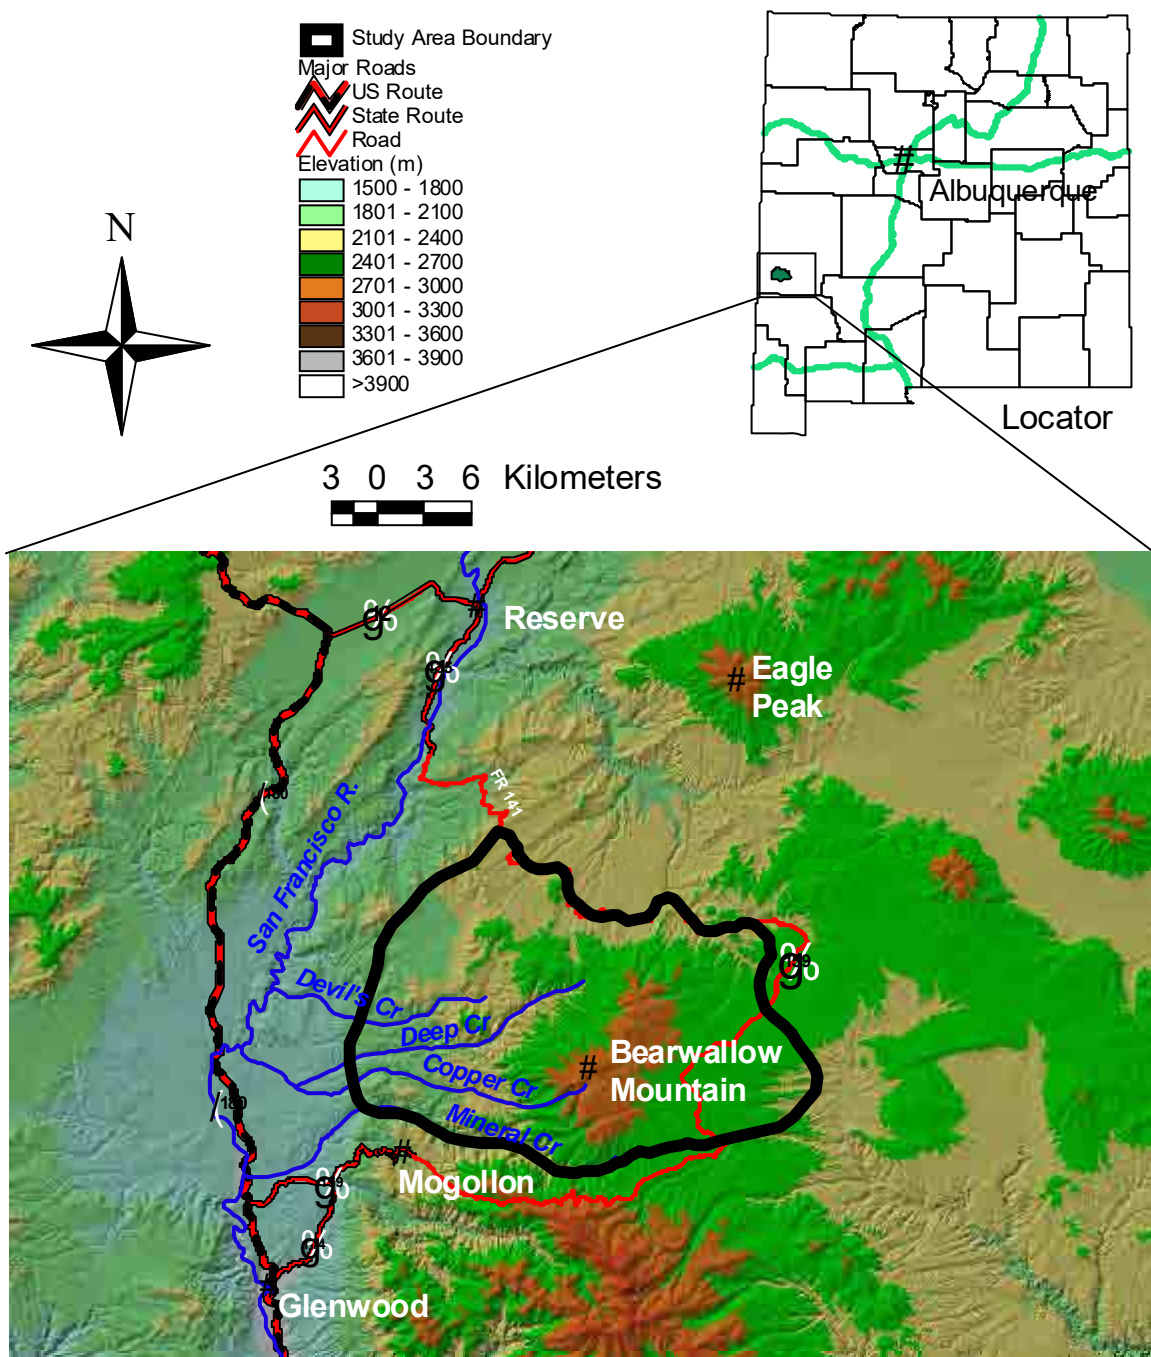

Figure 3-2. Location of the Southern Study Area of the Black Bear Study in New Mexico showing relationship to major roads, towns, and terrain.

During the study period, cattle grazing and recreation were the primary land uses. Historically, logging was also a dominant land use in this area, but during the 1990's, timber harvest was very limited within the study area. It consisted of 1 commercial timber sale on Corner Mountain and limited firewood cutting. Prior to the 1990's, much of the forested area was selectively logged or cleared for pasture, therefore most forests were second-growth. Some old-growth forests persisted, especially in steeper canyons. Numerous constructed dirt tanks were found within the area, providing permanent or seasonal water for cattle and wildlife.

Topography was diverse on the SSA, but elevations were lower than the NSA. Elevations ranged from approximately 1,750 m (5,740 ft) on the west side of the study area to 3,035 m (9,954 ft) on Bearwallow Mountain. Dominant habitat types coincided with those described for the NSA, with some variation in species composition. The high elevation bristlecone pine-limber pine forest and alpine community of the NSA were not present on the SSA.

The area included numerous permanent streams draining into the San Francisco River, including Devils Creek, Deep Creek, Copper Creek, and Mineral Creek. Many of the smaller streams on the area were ephemeral, drying out annually or in drought years.

Climate varied by elevation within the study area (Table 3-1). Mean January temperatures were below freezing at upper elevations, but above freezing at lower elevations. Snowfall was lower than that of the NSA. July temperatures were generally mild, but warmer than the NSA. Most rainfall occurred during July-August and rates were similar to the NSA.

The SSA was located within GMU 16A, and was open to bear hunting throughout the study period. Historically, hunting intensity in the region was moderate to high.

CHAPTER 4

CAPTURE OUTCOMES AND PHYSICAL CHARACTERISTICS

The objectives of the field study required us to capture a large sample of black bears and place radio-transmitters on many individuals. As a prelude to later chapters, we report the methods for our field investigations, including trapping efforts, den investigations, and radio-telemetry monitoring. We also include information on physical characteristics of bears obtained during these activities.

METHODS

Throughout the study period, our trapping efforts were primarily focused on the capture of previously unmarked females, to meet a target of 25 radio-transmitter equipped females monitored each year for reproductive success. During later years, much of the trapping effort was aimed at recapture of individuals requiring refitting or removal of their radio-collar.

Throughout the active season (primarily May-October), we captured bears using foot snares and culvert traps. Traps were examined by 1200 hours each day to prevent excessive stress to captured animals. All snared bears and most culvert-trapped bears were chemically immobilized and handled, however some recaptured bears caught in culvert traps were released without handling. Immobilizing drugs were administered using syringe poles. Captured bears were immobilized using 1 of 2 mixtures of immobilizing agents. Most often, we used a 2:1 mixture of ketamine hydrochloride (Ketaset, Fort Dodge Animal Health, Overland Park, Kansas) and xylazine hydrochloride (Rompun, A. H. Robins Co., Richmond, Virginia) at a combined dosage rate of 6.6 mg/kg (3mg/lb) estimated body weight (Addison and Kolenosky 1979). Under some circumstances, we used tiletamine hydrochloride + zolazepam hydrochloride (premixed as Telazol, A. H. Robins Co., Richmond, Virginia) at a dosage rate of 5.5 mg/kg (2.5mg/lb) estimated body weight (Gibeau and Paquet 1991). Use of Telazol was not ideal for our trapping regime because the protracted recovery period, characteristic of this drug, limited our ability to handle multiple bears per day.

We monitored respiration, pulse, and body temperature during immobilization. Ointment was applied to the eyes of bears to inhibit drying. Blindfolds were used and loud sounds were minimized to reduce unnecessary disrupting stimulus. We remained with immobilized bears until recovery was observed.

Sex of captured bears was determined from external genitalia. Black or brown color phase was noted for each bear, based on the color of the guard hairs and the underfur. Coat condition was rated as good or poor/shedding. For all bears, we recorded chest girth, body length, neck circumference, foot pad

length/width, and weight (when possible). For female bears, we noted vulval swelling, teat length/width, teat color, occurrence of lactation, evidence of suckling (swollen teats or hair matting), and presence of offspring.

Approximate age of bears was estimated from tooth eruption/wear (Jonkel 1993) and size. A vestigial premolar tooth was extracted from bears ≥ 1 year old for age determination using cementum annuli counts (Stoneberg and Jonkel 1966, Willey 1974). Age class was assigned as follows: cub (< 1 year), yearling (1 year), subadult (2-4 years), and adult (≥ 5 years).

We marked each bear with numbered, colored eartags (Allflex USA, Dallas, TX) and we tattooed the same number on an inner, upper lip. We placed radio-transmitters on all females captured, except during 1999-2000 when our target sample size of 25 had been met. We placed radio-transmitters on adult males as needed to maintain a sample of approximately 10 individuals each year. During the first year of the study, most subadult males were also given radio-transmitters. The practice of collaring captured subadult males was terminated after 1993, in favor of placing transmitters on yearling males and females in the den. Adult-sized collars (mod-500 or mod-505, Telonics, Tempe, Arizona) were placed on bears weighing over 23 kg (50 lbs). Bears weighing less than 23 kg were fitted with Telonics mod-400 collars, expandable subadult collars (Ursus Technologies, Williamsburg, Virginia), or ear-tag transmitters (Advanced Telemetry Systems, Isanti, Minnesota). Collars were fitted to allow for growth and cotton spacers were attached to ensure collars would fall off in the event of transmitter failure (Hellgren et al. 1988).

We visited dens of radio-transmitted adult females each year to ascertain their reproductive status. If offspring were present, we attempted to handle all bears in the den, however inaccessibility sometimes prevented it. If offspring were not present, females were usually handled only if necessary to change or refit collars. Dens of males and subadult females were visited annually or biannually to change or refit collars as necessary. Adult, subadult, and yearling bears requiring handling were immobilized using Telazol. We elected to use Telazol for den work because of its reduced tendency to depress heart rate and respiration compared to Ketaset/Rompun. Cubs were handled without immobilization. Typically, we did not remove adult bears from dens, unless it was necessary to reach their head or to reach offspring, however yearlings and cubs were removed from dens for handling. Weights and other measurements were obtained from all bears when possible. Den investigations were conducted between January and April, however we limited handling of cubs to March and April when our handling would have negligible impact on their survival.

We monitored radio-collared bears from fixed-wing aircraft on a 14-day schedule during the active season (weather permitting). During fall and spring months, we attempted to increase the flight schedule to 7-10 days for obtaining

den entrance and den emergence data. During winter months, monitoring of bears was reduced while the bears remained in their dens. We recorded locations using Universal Transverse Mercator (UTM) grid coordinates to the nearest 0.1km, on United States Geological Survey (USGS) 7.5-minute maps. We estimated aerial telemetry error by comparing locations obtained by telemetry to actual locations verified by ground investigation. These locations included those of shed transmitters, bear mortalities, and blind tests.

RESULTS AND DISCUSSION

Trapping Success, Den Investigations, and Monitoring

Between September 1992 and June 2000, we captured 300 bears (103 females, 195 males, 2 unknown sex) 517 times. Individual bears were captured 1-9 times with a mean of 1.5 captures/bear. First-time captures, total captures, and capture success were similar between study areas (Table 4-1). History and circumstances of all bears handled are described in Appendix A.

Table 4-1. Black bear trapping success on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992-2000.

Area	Category	No. Trap-nights	No. Captures		Capture Success (trap-nights/bear)	
			First-time	Total	First-time	Total
NSA	Snare	1338	64	116	20.9	11.5
	Culvert	1564	76	162	21.7	9.7
	Total	2902	140	278	20.7	10.4
	Females		49	73	59.2	31.9
	Males		91	204	39.8	14.2
SSA	Snare	1552	79	116	19.6	13.4
	Culvert	2230	81	123	27.5	18.1
	Total	3782	160	239	23.6	15.8
	Females		54	73	70.0	51.8
	Males		104	164	36.4	23.1

Between January 1993 and April 2000, we handled or observed 339 bears (178 females, 137 males, 24 unknown sex) in dens 680 times. Individual bears were handled or observed 1-8 times with a mean of 2.0 observations/bear. Successful den investigations included 282 individual adults (233 females, 49 males), 99 subadults (65 females, 34 males), 95 yearlings (45 females, 44 males, 6 unknown sex) and 204 cubs (94 females, 91 males, 19 unknown sex). In addition to these successful den investigations, we attempted to visit the dens of 24 other bears, but were unsuccessful because of inaccessibility of dens ($n = 14$), and prior emergence from the den ($n = 10$).

During 1992-1999, we placed 409 radio-transmitters on 316 bears (181 females, 135 males). Transmitters included 287 adult-sized collars, 27 subadult-

sized collars, 55 expandable subadult collars, and 40 ear-tag transmitters. We obtained 5,723 radio-telemetry locations.

Telemetry error was estimated from 105 locations verified with ground investigation. On the NSA, error ranged from 50-1,100 m with a median of 200 m, and a mean of 285 m ($n = 23$). On the SSA, error ranged from 50-3,780 m, with a median of 505 m and a mean of 784 m ($n = 82$).

Physical Characteristics

Color phase was recorded for 471 bears on 918 occasions. Most bears (75%) were brown-phase. Confidently assigning a bear to a color phase was sometimes difficult, due to color differences in underfur, especially when coats were shedding. Black-phase bears were identified by their black guard hairs, but often had gray to brown underfur. Within the brown-phase, we observed hues ranging from blonde to cinnamon to dark chocolate or liver color. Due to bleaching and shedding, the hue of brown-phase individuals was observed to vary, depending on season. Many bears with light-colored coats during spring and summer were observed with dark brown coats in the fall or winter. Color phase has been described as changing for an individual (Beck 1991), but we found no definitive evidence of such change. We believe any recorded changes in color phase were due to seasonal changes in hair condition (shedding, bleaching), different conditions during observation (time of day, lighting), and differences in observers.

Percent color phase did not differ by sex ($X^2 = 0.03$, $df = 1$, $P = 0.85$, $n = 471$), but differed by study area ($X^2 = 35.5$, $df = 1$, $P < 0.001$, $n = 471$). On the NSA, 83% of females and 84% of males were brown phase. On the SSA, 58% of females and 64% of males were brown phase.

Coat condition varied throughout the year. Almost all bears (98%) had good coat condition during fall months (September-October, $n = 132$) and during the denning period (January-early April, $n = 326$). During May-August, we observed shedding or poor coat condition on 18-40% of bears ($n = 267$), with the highest proportion in July.

We obtained active-season weights or measurements for 280 individuals on 333 occasions. Weights and measurements differed among sex and age categories (Table 4-2). Mean weight of males increased significantly between cub age and 6-7 years, when mean weight appeared to level off (Figure 4-1). Mean weight of females increased between cub age and 2-3 years, when a gradual increase in weight was observed by age. A significant difference in male and female weights was observed by the ages of 2-3 and this deviation increased with age. Means for all other measurements showed similar trends (Figure 4-2).

Table 4-2. Mean and range for weights and measurements, by age category, of black bears recorded during the trapping season (May-October) on the Northern and Southern Study Areas, New Mexico, 1992-1999.

We obtained den-season weights or measurements for 183 cubs or yearlings on 238 occasions (Table 4-3). At approximately 4-8 weeks of age, mean weight of cubs was 2.0 kg, and mean weight did not differ by sex ($t = -0.5$, $df = 165$, $P = 0.64$, $n = 167$). At approximately 12-14 months, mean weight of

yearlings was 20.8kg, and it did not differ by sex either ($t = -0.5$, $df = 36$, $P = 0.63$, $n = 38$).

Table 4-3. Mean and range for weights and measurements of cub (<1 year) and yearling (1 year old) black bears, recorded during the den season (January-April) on the Northern and Southern Study Areas, New Mexico, 1992-1999.

Measurement	Age	<i>n</i>	Mean	Range
Weight (kg)	Cub	167	2.0	1.0 - 3.8

	Yearling	18	101	80 - 140

We observed 1 unusual bear on the NSA, first captured as a 3-year-old and monitored for 3 years. This bear exhibited male and a female external genitalia. It was not clear whether this hermaphrodite was reproductively functional as either sex. The bear was not observed to produce cubs, but it was once observed in the company of a marked female bear during the mating season. Its size was also more closely aligned with that of males. Because of the lack of offspring and its large size, we treated this individual as a male for most analyses, such as survival and home range.

Research-related Injury, Mortality, and Den Disturbance

During 517 captures, bears sustained 1 mortality (0.2%) and 10 injuries (1.9%). The mortality was sustained by a snared subadult female killed by another bear, and 1 injury (severed toe and claw) was sustained by a snared adult male as he defended himself from another bear. The other 9 injuries were the result of bears chewing their snared foot and severing toes and/or part of the main pad. Two incidents occurred during 1992 on the NSA, and 7 occurred during 1993 or 1995 on the SSA. During 1993 on the SSA, trapping teams sometimes separated to examine snares and, after meeting up, returned to sites where bears were captured. We suspect this action may have contributed to some of the first incidents of foot chewing on the SSA, and this practice was immediately discontinued when snares were used. It appeared most other

incidents occurred when function of the swivel mechanism was inhibited, however cause could not be identified in all cases. Factors contributing to loss of swivel action included: use of stacked log cubbies; use of small, but live plant materials as part of the cubby; and failure to remove small shrubs from the area reachable by the snared bear. We discontinued use of stacked-log cubbies and only used dry, brittle material in cubby construction. Complete elimination of these factors after 1995 resulted in no further incidents of foot chewing. The addition of bungee cords and hood springs to snares during 1995-1997 also may have reduced injuries.

In traps and dens, we immobilized 762 bears and experienced 3 handling mortalities (0.4%). We believe an adult male died from reaction to the immobilizing drugs because a necropsy revealed the bear had sustained internal injuries prior to capture and it also had a congenital heart defect. An adult female with a debilitating case of sarcoptic mange died during den handling. Probably as a result of the infection and blindness, she was very emaciated and weak. The dose of immobilizing drug was appropriate for a healthy bear, however it may have been too much for a bear in her poor condition. Another adult female died when her radio-collar blocked her airway when she became immobile in the den. The problem was not observed quickly enough, and her breathing and heartbeat stopped. Cardio-pulmonary resuscitation was attempted for 35 minutes, however she was not revived.

In 369 uses of radio-collars, 8 uses (2.2%) resulted in severe subdermal injury when bears outgrew the collar. One injury involved an adult male wearing an adult-sized collar. Another injury involved a maturing female wearing an adult-sized collar. The 6 other injuries occurred when juvenile bears were fitted with expandable collars. Injuries occurred both when collars expanded as designed ($n = 3$) and when collars failed to expand ($n = 2$). Four of 6 injuries resulted from collars worn >2 years because we were prevented from removing them by inaccessible dens, unsuccessful trapping, and loss of signal.

During 414 den visits, there were 33 instances when bears fled dens upon our approach. Nine of these instances (27%) involved adult females with offspring (5 with cubs, 4 with yearlings). Following our disturbance, 4 of 5 females with cubs were believed to have returned to their dens. One female abandoned a single cub, which was removed from the den and cross-fostered with another adult female with cubs. When disturbed, 3 of 4 females with yearlings fled without their offspring, while 1 of 4 fled along with her single yearling. One of the 3 females that fled without their yearlings returned to the den, while 2 did not return. It was unknown if 1 of these females reunited with her offspring, but the other was handled in a second den and her yearlings were not with her. One female on the NSA fled her den each time we visited it, including 4 times when we immobilized her as she fled the den. This bear accounted for 4 of the 9 incidents described above (3 with cubs, 1 with yearlings).

CHAPTER 5

VARIATION IN MAST PRODUCTION

A positive correlation between food abundance and black bear reproductive success has been widely reported, based on annual variability in foods (Jonkel and Cowan 1971, Rogers 1976, Eiler et al. 1989, Elowe and Dodge 1989, McLaughlin et al. 1994, Miller 1994), geographic variability in foods (Schwartz and Franzmann 1991, McLaughlin et al. 1994, Miller 1994) and differential feeding behaviors among bears (Rogers 1976, Elowe and Dodge 1989). In most studies, availability of hard mast (e.g., acorns and beechnuts) and soft mast (e.g., huckleberries and blueberries) appeared to have the greatest influence on reproduction. Reproductive success also has been linked to female nutritional condition (Kolenosky 1990, Noyce and Garshelis 1994, Samson and Huot 1995).

A first step in understanding New Mexico black bear ecology and population dynamics was to verify use and availability of mast species. We investigated bear foraging habits and variation in mast production on the 2 study areas during 1993-2000. Our objectives were to: (1) identify important mast species consumed by New Mexico black bears; (2) document annual variation in mast production of these species; (3) determine relationships between weather parameters and mast production; and (4) evaluate the feasibility of implementing statewide mast production surveys.

METHODS

Foraging Habits

We quantified bear foraging habits from scat analysis and observation. During 1992-1995, we collected scats incidental to field work. In addition, we visited selected ground locations identified from aerial telemetry to collect scats and observe bear sign. We recorded approximate date of deposition, location, and habitat descriptions for each scat. Data on other bear sign and activity also were noted. We analyzed scats using methods described by Hatler (1972) and visually estimated percent volume of each food item. We summarized scat contents during 3 seasons: premast (den emergence-20 July), early mast (21 July-15 September), and late mast (16 September-den entrance). During 1995-1996, we documented general trends in foraging habits by recording observations of bear sign and identifying primary contents of scats in the field.

Study Area Mast Surveys

We conducted mast production surveys to quantify annual variation in food abundance on the 2 study areas. Surveys were limited to species contributing most to bear diets, based on scat analysis, field observations, and

previous studies in the Western U.S. On the NSA, surveyed species included Gambel oak (*Quercus gambelii*), wavyleaf oak (*Q. undulata*), pinyon (*Pinus edulis*), Rocky Mountain juniper (*Juniperus scopulorum*), one-seed juniper (*J. monosperma*), and chokecherry (*Prunus virginiana*). On the SSA, surveyed species included Gambel oak, gray oak (*Q. grisea*), pinyon, alligator juniper (*J. deppeana*), Utah juniper (*J. osteosperma*), and orange gooseberry (*Ribes pinetorum*). Timing of surveys coincided with the period just prior to peak ripening (mid August to mid September), to ensure most fruit were fully formed, but losses to wildlife were minimal.

We established mast survey routes across study areas designed to encompass variation in elevation and aspect. Survey routes followed roads, jeep trails, or foot trails, and ranged from approximately 0.8-8.0 km (0.5-5.0 mi), depending on the extent of appropriate habitat. On each transect, we designated 2-10 survey sites at predetermined intervals of 0.2-1.6 km (0.1-1.0 mi). At each site, we walked 10 paces away from the road and classified production for the closest 1-10 (usually 5) plants of each species. The same survey routes and sites were revisited each year, with the same number of plants classified at each site. One hundred individual plants were classified for oaks, junipers, pinyon, and gooseberry. Forty individual plants were classified for chokecherry. All species, except for chokecherry, were surveyed on 2-5 separate survey routes.

Ratings were assigned as described by Graves (1980): no visible fruit = 0; fruit visible after very close inspection = 2; fruit readily visible, but not covering entire plant = 4; or fruit readily visible and covering entire plant = 8. This sequence of numbers was chosen because it roughly represented a minimum ratio of fruit/plant among the 4 classifications.

Analyses were performed using SPSS statistical software (SPSS, Chicago, Illinois). Mean ratings were calculated for each species by year. Because the rating data were ordinal, the Kruskal-Wallis (KW) rank procedure was used to test for annual differences, by species and genera. The Student-Newman-Keuls (SNK) test was then used to detect differences among mean ranks and identify homogenous subsets (pool years). We used mean ratings of homogenous subsets to characterize mast production by species or genera, with the following ranges of values as guidelines: 0.0 - 1.4 = failure; 1.5 - 2.4 = poor; 2.5 - 3.9 = moderate; 4.0 - 4.9 = good; 5.0 - 6.0 = excellent. These ranges of values were flexible under certain circumstances. For example, if the mean rating of subset A was 1.6 and the mean rating of subset B was 2.4, subset B might be designated as "moderate" to differentiate it from subset A.

Relationship with Weather Variables

Forward and backward stepwise linear regressions, using S-PLUS 2000 statistical software (Insightful Corporation, Seattle, Washington), were performed using average oak mast index as the response variable. Explanatory

environmental variables considered included temperature, last frost date, seasonal rainfall, and seasonal Palmer Drought Stress Index, all varying both between study areas and from year to year on each study area. Additional statewide variables, which differed from year to year but were the same for both study areas each year, were annual total wildland fire acres, winter El Nino state estimated by NOAA (coded as +1 for warm El Nino conditions, -1 for cold or La Nina conditions, and 0 for neutral). One-year time lags were considered. Analyses were run using 1993-1999 mast observations, to be tested with 2000 observations, and also with 1993-2000 mast observations.

District Mast Surveys

During 1999-2000, we distributed simplified mast survey forms to New Mexico Department of Game and Fish officers whose districts included bear habitat. For these surveys, mast production was assessed at the genera level for oaks, junipers, and pinyon. Officers were asked to observe mast production any time during September, coincident with other field activities, and answer the following questions for each genera (no specific training given to officers):

- (a) What percentage of plants had fruit? (circle one)
< 25% = 1; 25-50% = 2; 51-75% = 3; > 75% = 4
- (b) In general, of plants bearing fruit, how would you characterize the number of fruit per plant? (circle one or two)
scarce = 2; moderate = 3; abundant = 4; super abundant = 5
- (c) How would you characterize overall fruit production? (circle one)
mast failure = 1; poor = 2; moderate = 3; good = 4; bumper crop = 5

For summarizing data, the subjective criteria were substituted with numerical variables, as shown above. Numerical values to questions (a) and (b) were multiplied to produce a mast production "score". Numerical answers to question (c) were used as mast production "assessment". Officer surveys were summarized on a regional basis. Mean scores and assessments were calculated for each of the following mountain regions (see Chapter 11):

- San Juan complex (San Juan and Jemez Ranges, Navajo Dam area)
- Sangre de Cristo complex
- Central (Sandia, Manzano, Zuni, and San Mateo ranges)
- Gila complex (Mogollon, Tularosa, Mimbres, Gallinas, and Animas ranges)
- Southeast (Sacramento, Capitan, and Guadalupe ranges)

We used Spearman's rank correlation procedure to compare our mast survey results to scores and assessments provided by officers from the 2 Districts encompassing the study areas.

Follow-up Telephone Survey

We conducted a follow-up telephone survey during October-December 1999. Personnel from NMDGF were asked several questions regarding the ease of the survey, the time spent on the survey, and their willingness to participate in the survey on an annual basis.

RESULTS

Foraging Habits

Analysis of scats collected during 1993-1995, indicated most of the annual diet was plant matter on both study areas (Table 5-1). Diets during the pre-mast season (den emergence – 20 July) were dominated by grasses and forbs. On the NSA, most of diet was grasses, including *Poa*, *Festuca*, and *Muhlenbergia*. On the SSA, grasses and sedges were most dominant, including *Poa*, *Festuca*, *Muhlenbergia*, *Piptochaetium* and *Carex*. Forbs appeared to be more important on the SSA, and included vetch (*Vicia* spp.), peavine (*Lathyrus* spp.), and golden pea (*Thermopsis rhombifolia*). Blossoms of New Mexico locust (*Robinia neomexicana*) also were consumed. On both study areas, ants (Formicidae) constituted a significant portion of the pre-mast season diet. Unlike the NSA, soft mast was a significant portion of the pre-mast diet for bears on the SSA. Mast species consumed included alligator juniper, Utah juniper, squawroot (*Conopholis alpina*), gooseberry (*Ribes* spp.), and hawthorn (*Crataegus* sp.).

Mast species became more dominant in the diets of bears on both study areas during the early mast season (21 July – 15 September), and consumption of vegetation and ants was reduced. On the NSA, acorns of Gambel oak and wavyleaf oak were most common, comprising 56% of the scat volume. Other mast species consumed included chokecherry, squawroot, and gooseberry. On the SSA, important species consumed included juniper berries, acorns, pinyon nuts, gooseberries, prickly pear fruit (*Opuntia* spp.), and squawroot.

During the late mast season (16 September – den entrance), mast was the dominant food on both study areas. On the NSA, 88% of the scat volume was mast, with acorns comprising 87%. On the SSA, 82% of the diet was mast, with acorns accounting for 36%. Other species included juniper and prickly pear.

Observations and field examination of scats during 1995-2000 concurred with scat analysis findings reported above. On the NSA, grasses and insects were the most commonly observed pre-mast foods. During the early and late mast seasons, observations indicated acorns were the primary food sought by bears. However, consumption of 5 other soft mast species, not found during 1992-1995, were recorded. During the early mast season bears were observed to forage on squawbush (*Rhus trilobata*), wild plum (*Prunus americana*), and kinnikinnick (*Arctostaphylos uva-ursi*), and during the late mast season bears

were observed to forage on Rocky Mountain juniper and one-seed juniper. Most juniper scats were encountered at den sites, indicating this food was primarily consumed during the late fall, just prior to den entry.

^d Trace amounts

On the SSA, observations during 1996-2000 also concurred with findings from scat analysis, with 1 possible exception. During 1997 and 1999, we observed bears feeding on juniper berries throughout the active season, beginning as early as April. These observations indicated juniper berries constituted more than 10% of the spring and summer diet as observed from scat analysis. Consumption of 2 other soft mast species, Wright siltassel (*Garrya wrightii*) and squawbush), was noted during 1996-2000.

Study Area Mast Surveys

Mast production varied annually for all species on both study areas ($P < 0.001$). Production of Utah juniper was most variable of the species surveyed, with crops ranging from failure to excellent (Table 5-2). Production of Gambel oak, gray oak, alligator juniper, and orange gooseberry also was variable, with crops ranging from poor to excellent or failure to good. Production of wavyleaf oak, Rocky Mountain juniper, and pinyon was generally low, with only 1 of 8 years exceeding a poor rating on either study area. Although production of one-seed juniper varied among years, all production was rated as failure.

Within most years on each study area, mast production varied by species or genera. With the exceptions of 1997 (NSA) and 2000 (SSA), at least 1 species produced mast in excess of poor each year. We observed only 1 year of outstanding mast production, when production of all species was at least moderate. This occurred on the SSA in 1998. Production of combined oak varied annually on both study areas. Combined juniper production varied greatly on the SSA, but juniper failure occurred every year on the NSA.

Relationship with Weather Parameters

Mast patterns differed between the study areas. The SSA had a higher correlation among species, but more variability within species over time. Analysis focused on environmental associations with oak mast, because oak had a consistent relationship to parturition (see Chapter 6).

For the NSA for 1993-1999, the best regressions with average oak mast used last frost date and El Nino state. Both a regression with frost date alone and a regression with both variables predicted good mast for 2000, as observed, but the regressions were not usable. The single variable model was not significant ($P = 0.185$) and the independent variables were negatively correlated (-0.60) in the model with both variables. For the NSA for 1993-2000, reasonable models were found with a single variable (last frost date) and 2 variables (last frost date and winter El Nino: Table 5-3). With the addition of the year 2000 data points, the correlation between frost date and El Nino (0.07) was eliminated. Both models leave much of the variation in oak mast unexplained, and neither correctly predicts the single NSA mast failure in 1993.

Table 5-2. Mast production survey results for 10 woody plant species examined on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993-2000.

^a Individual plants were visually rated using the following criteria and mean ratings are shown: no visible fruit = 0; fruit visible after very close inspection = 2; fruit readily visible, but not covering entire plant = 4; or fruit readily visible and covering entire plant = 8.

^b Letters refer to the following relative scale for mast production: F = Failure, P = Poor, M = Moderate, G = Good, or E = Excellent. For each species, annual estimates designated with distinct letters were different based on the Kruskal-Wallis rank sum and Student-Newman-Keuls tests ($P \leq 0.10$).

For the SSA, good regressions with average oak mast were found with either winter El Nino state or average April temperature for 1993-2000 (Table 5-3). Models for 1993-1999 were nearly identical. El Nino and April temperature are strongly negatively correlated (-0.76 for 1993-1999 and -0.80 for 1993-2000), so the 2 models are related. The El Nino model correctly predicts the mast failures in 1996, 1999, and 2000, but not in 1994. The April temperature model correctly predicts the mast failures in 1996 and 2000, but not in 1994 or 1999.

Table 5-3. Regressions predicting average oak mast production from weather parameters for the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993-2000.

District Mast Surveys

Combining all genera, mast scores and evaluations were highly correlated (Spearman's $r = 0.82$, $P < 0.001$, $n = 58$), indicating both criteria (Question a*b vs. Question c) produced similar relationships. On the 2 study areas, scores were highly correlated with survey results (Spearman's $r = 0.0.72$, $P = 0.008$, $n = 12$), as were assessments (Spearman's $r = 0.76$, $P = 0.004$, $n = 12$), but scores displayed less variation at the lower levels.

Summarizing data for the 5 mountain regions, mast production was either failure or poor for all genera (Table 5-4). However, a few districts reported moderate and good production of oak and juniper. Some districts also reported moderate pinyon production, but none reported good production.

Phone Survey

Twenty-two NMDGF officers were interviewed in the follow-up phone surveys, but 3 (14%) did not complete mast surveys in their districts. One respondent thought the survey pertained only to an adjacent district; 1

respondent felt there was only marginal bear habitat in his district, therefore a survey was not necessary; and 1 respondent said he did not have time to participate.

Nineteen (86%) of the 21 NMDGF officers interviewed completed mast surveys in their districts. Summary of responses to 6 questions indicated that most respondents (94%) said it was easy to evaluate mast production using the criteria provided, while 1 respondent (5%) said it was moderately difficult. More than half of respondents (67%) said it was easy to evaluate their entire district, while several respondents (28%) said it was moderately difficult, and 1 respondent (6%) said it was difficult.

Similarly, more than half of respondents (64%) did not believe their districts needed to be subdivided for this survey, while several respondents (36%) believed districts should be subdivided. Two NMDGF personnel subdivided their districts by Game Management Unit (GMU) for the mast survey, and several respondents also suggested this option during the phone surveys. One respondent identified 4 separate sections of bear habitat within a district, but said these areas did not correspond with GMU boundaries. One other respondent suggested adding a section on the form for a description of the areas surveyed.

Almost all respondents (95%) said they were able to complete the surveys in the course of their usual duties; only 1 respondent (5%) said he had to devote specific time to the survey, but he added that it was not a large time commitment. All respondents agreed mast survey information is important for bear management, but several respondents voiced concern over how data would be used, or whether the surveys were detailed enough to be useful. All respondents (100%, $n = 20$) said they would be willing and able to participate in the survey on an annual basis. One respondent suggested the survey period be extended into October, since mast is still available, and officers spend many hours patrolling during that month.

DISCUSSION

Oak production was highly variable on both study areas, especially that of Gambel oak and gray oak. On the NSA, only 1 oak failure was recorded in 8 years of study, however 4 oak failures were recorded on the SSA in the same period. Continuation of mast surveys may allow us to determine if these observed frequencies of oak failure are consistent within the 2 regions of the state. Production was highly variable for Utah and alligator juniper, but was consistently low for Rocky Mountain and one-seed-juniper. If further surveys indicate a consistent trend, the lack of abundant juniper berries throughout northern New Mexico, where Utah and alligator juniper are largely absent, may have important implications for bear population dynamics. According to popular thought, abundant pinyon production occurs only once every 7 years. Results of

our surveys concur with that belief, in that there was only 1 year of moderate production on each study area in 8 years. Results of statewide mast surveys showed, in most areas, mast production was relatively low in both 1999 and 2000.

The variables correlated with oak production were temperature and El Nino winter state, suggesting that a combination of moisture and temperature conditions for the winter and spring influence mast conditions in the following fall. Each of the oaks surveyed were species that flower and fruit within the same year, and we observed oak flowering from mid May-early June. Models for the NSA and SSA used different variables, and no useful relationship was found that applied to both areas. All of the models failed to predict at least 1 mast failure year; none predicted mast failure when no failure was observed.

MANAGEMENT IMPLICATIONS

Environmental cues did not provide a prediction of mast conditions adequate for bear management needs. Results of simplified surveys conducted by NMDGF officers were highly correlated with our more intensive survey results, indicating subjective criteria were adequate to distinguish variation in mast production. Results were most consistent with a score of relative numbers of fruit/plant and relative numbers of plants bearing fruit. Most officers indicated the criteria were reasonably easy to use and said they were able to complete the surveys in the course of their usual duties. Although most NMDGF officers were comfortable making assessments for their entire districts, others felt subdivision of their district into sections or Game Management Units made the assessments more realistic. Quality assessments of regional mast production will always be improved with higher sample sizes, therefore subdivision of districts may be preferable to district-wide surveys.

^aOfficers assessed production of oak, juniper, and pinyon production using the following subjective criteria: mean number of fruit/plant on a scale of 1-4 (a), percent of plants bearing fruit on a scale of 1-4 (b), and overall production on a scale of 1-5 (c). Scores (a*b) were highly correlated with more intensive surveys conducted concurrently (Spearman's $r = 0.0.72$, $P = 0.008$, $n = 12$), and ratings were calculated using the equation of the line. Letters refer to the following relative scale for mast production: F = Failure, P = Poor, M = Moderate, G = Good, or E = Excellent.

CHAPTER 6

REPRODUCTION AND CUB SURVIVAL

Maintenance and growth of wildlife populations are closely tied to reproductive output. Collectively, bear species exhibit some of the lowest reproductive rates among terrestrial mammals (Bunnell and Tait 1981). In many previous bear studies, a positive correlation between food abundance and black bear reproduction has been reported, based on annual variability in foods (Jonkel and Cowan 1971, Rogers 1976, Eiler et al. 1989, Elowe and Dodge 1989, McLaughlin et al. 1994, Miller 1994), geographic variability in foods (Schwartz and Franzmann 1991, McLaughlin et al. 1994, Miller 1994), and differential feeding behaviors among bears (Rogers 1976, Elowe and Dodge 1989). Reproductive success also has been linked to female nutritional condition (Kolenosky 1990, Noyce and Garshelis 1994, Samson and Huot 1995). Understanding the reproductive rates of black bears in New Mexico, as well as the factors that influence success, is important for monitoring population trend. On an annual basis, collection of actual data on bear reproduction would probably be labor-intensive and cost-prohibitive. However, documentation of annual variation in food abundance may serve as an index to bear reproductive success.

We investigated black bear reproductive success on the 2 New Mexico study areas during 1993-2000. Our objectives were to (1) document black bear reproductive parameters, including age of primiparity, natality, cub survival, recruitment, and litter interval; and (2) investigate relationships between mast production and reproductive parameters.

METHODS

Data on natality, litter size, and recruitment were collected during annual den investigations of radio-collared bears. We visited dens of adult females each year to ascertain their reproductive status. Dens of 2- or 3-year-old bears were visited annually or biannually to change or refit collars as necessary. We obtained cub survival data by revisiting dens of females whose cubs were handled or observed the previous year. Cubs were assumed to have died if they were absent from the den as yearlings, or if their mother died prior to 1 July in their birth year. Cubs whose mother died after 1 July and cubs whose fate was unknown (due to mother shedding collars, lost signals, inaccessible dens, etc.) were excluded from analyses.

We estimated mean age when the first litter is produced (age of primiparity) by constructing a cumulative table of ages for bears that had never give birth versus ages of bears when they first produced cubs.(Garshelis et al. 1998). The minimum age of primiparity was judged to be 4 years old, because no 1-, 2-, or 3-year-old bear was observed with cubs in the den ($n = 76$), and no

1- or 2-year-old bear was observed in estrus when captured between May and September ($n = 21$). We constructed the cumulative table by first including all bears whose reproductive status was verified during annual den investigations beginning at age 4 ($n = 36$). We also included females captured at age 4, whose reproductive status was judged from teat measurements, weight, lactation, or observation of cubs ($n = 11$). Among females captured at age 5, we included bears judged to never have given birth from teat measurements and weight, but entered them into the table only for later den investigations ($n = 2$). To backdate them to age 4 or include them for the year of capture would bias the sample against bears captured with their first cubs, because we could not distinguish first litters from subsequent litters for bears captured at ages >4 years. We used the same procedure to estimate mean age of primiparity relative to mast production during the previous fall (year-1).

We tested for variation in reproductive success relative to mast production using Mann-Whitney (MW), Kruskal-Wallis (KW), Chi-square, and Student-Newman-Keuls (SNK) tests. We report specific p-values associated with any differences declared. Annual reproductive events for the same female were treated as independent observations, as were offspring from the same female. When possible, we separated females into distinct subsets to lessen effects of any potential lack of independence. Variation in reproductive parameters was investigated relative to mast production during the previous fall (year-1) and relative to fall mast production 2 years previous (year-2). Mast production categories included combined oaks, combined junipers, pinyon, and softmast (chokecherry or gooseberry).

To construct a sample for estimating mean litter interval, we first included all bears whose interval was verified during annual den investigations ($n = 63$). We also included females whose interval was known from observation of offspring at capture ($n = 2$), and bears whose incomplete interval was known to be at least 3 years ($n = 7$). We included these latter bears in the analyses because long intervals were more difficult to document than short intervals. Reproductive status must be documented for at least 3 consecutive years to document a successful 3-year interval and at least 4 years for an unsuccessful 3-year interval. During this study, reproductive status was documented <3 times for 38% of individual bears ($n = 64$), reducing the likelihood of documenting longer intervals.

RESULTS

Age of First Birth

Age at birth of first litter was documented for 31 bears between 1992 and 2000, and mean age from this sample was 5.5 years. However, age(s) prior to primiparity were documented for another 18 bears aged 4-6. Ultimate age of primiparity was not documented among this sample because of collar removals

at the end of the study ($n = 6$), collar removal due to a wound ($n = 1$), mortalities ($n = 4$), shed transmitters ($n = 4$), and lost signals ($n = 3$).

Among bears observed at each age that had not produced litters previously, only 9% of 4-year-old bears produced their first litters, while 40% of 5-year-olds, 67% of 6-year-olds, 75% of 7-year-olds, and 100% of 9-year-olds produced their first litters (Table 6-1). Proportions differed among ages ($\chi^2 = 27.1$, $df = 5$, $P < 0.001$, $n = 97$), with 4-year-old females having the most significant residual. When this age was excluded, proportions did not differ among other ages ($\chi^2 P = 0.21$, $n = 51$). Proportions did not differ between study areas within any age ($X P \geq 0.47$). Accounting for the proportion of previously non-reproductive bears in the population at each age, analysis indicated 9% of bears produced their first litter at age 4, 37% at age 5, 36% at age 6, 14% at age 7, and 5% at age 9. The mean age of primiparity calculated from these percentages was 5.7 years. Mean age of primiparity was 5.8 years on the NSA and 5.7 years on the SSA. Although age of primiparity varied by 5 years among the entire sample, analyses indicated most bears (73%) produced their first litter either at age 5 or 6.

Table 6-1. Observed percent of previously non-reproductive female black bears (by age) that produced first litters, on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992-2000.

Area	Age (years) ^a						Mean age
	4	5	6	7	8	9	
NSA							
<i>n</i>	28	19	8	3	1	1	
% of <i>n</i> with first litters	11	37	63	67	0	100	
Cumulative % with first litter	11	44	79	93	93	100	
Incremental % with first litter	11	33	35	14	0	7	5.8
SSA							
<i>n</i>	19	11	6	1			
Percent of <i>n</i> with first litters	5	46	67	100			
Cumulative % with first litter	5	48	83	100			
Incremental % with first litter	5	43	40	17			5.6
Combined							
<i>n</i>	47	30	14	4	1	1	
Percent of <i>n</i> with first litters	9	40	64	75	0	100	
Cumulative % with first litter	9	45	80	95	95	100	
Incremental % with first litter	9	36	35	15	0	5	5.8

^a Proportions of previously non-reproductive bears that produced first litters were different among ages ($P < 0.001$), but were not different within ages between study areas ($P > 0.45$). Mean age at birth of first litter was calculated using incremental percentages.

Mean age of primiparity appeared to differ by oak production during the previous fall, however mean testing was not possible using this method. Mean age of primiparity following oak failure was 6.3 years. Mean age of primiparity

following poor, moderate, and good oak production was 5.7 years, 5.7 years, and 5.8 years, respectively.

Natality

Between 1993 and 2000, reproductive data were obtained during 268 den investigations of 80 female bears aged 4-27 years. We estimated natality (cub production) using observations from all females. In addition, we separated the sample into 2 categories: non-reproductive females (those never having produced cubs prior to the current observation) and eligible reproductive females (those having produced cubs prior to the current observation). We considered all bears unaccompanied by yearlings "eligible" for cub production.

Overall natality of female bears ≥ 4 years old was 0.77 cubs/female/year and parturition rate (percent of females with cubs) was 43% ($n = 268$). Overall there was no difference (0.85 vs. 0.67, MW, $Z = -1.4$, $P = 0.15$) in natality on the NSA versus the SSA (Table 6-2). Parturition rate also did not differ by study area ($X^2 P = 0.32$). Among previously non-reproductive females, natality was 0.53 cubs/female/year and parturition rate was 33% ($n = 87$). Neither rate differed by study area (MW $P = 1.0$, $X^2 P = 0.81$). Among previously reproductive females, natality was 1.4 cubs/female/year and parturition rate was 77% ($n = 112$). Natality among these female bears was higher on the NSA (1.6 vs. 1.2, MW, $Z = -2.3$, $P = 0.02$), as was parturition rate (62% vs. 37%, $X^2 = 4.8$, $df = 1$, $P = 0.04$).

Table 6-2. Natality and recruitment of female black bears determined from den investigations on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993-2000. Females were considered eligible for cub production if unaccompanied by yearlings in the den. Rates denoted by asterisks differed from others by reproductive history or study area ($P \leq 0.15$).

Within all categories of females, natality and parturition rate were positively associated with oak production during the previous year (Table 6-3). For all females and for reproductive females, natality was lower in years following acorn failures than all other years (KW $P < 0.001$, SNK $P = 0.05$), as was parturition rate ($X^2 P < 0.001$). Neither natality nor parturition rate differed relative to poor, moderate, or good oak production during the previous fall (KW $P \geq 0.37$, $X^2 P \geq 0.23$). Among previously non-reproductive females, natality varied by oak production (KW $P = 0.08$), however no distinct subsets were identified (SNK $P > 0.15$). Parturition rate was positively associated with oak production ($X^2 P = 0.10$), with the lowest rate associated with oak failure. However, among the previously non-reproductive females, strength of the test was limited by an age bias in the sample. Of the 18 previously non-reproductive females observed following oak failure, 13 (72%) were 4-year-olds, and 5 (28%) were aged 5 or 6. Following poor, moderate, and good oak production, 4-year-old females comprised 29% ($n = 45$), 40% ($n = 15$), and 0% ($n = 7$) of the sample, respectively. When 4-year-old bears were analyzed alone, natality was positively but weakly associated with oak production. Natality was 0.2 cubs/female/year following moderate oak production, but 0.0 following oak failure and poor production (KW, $X^2 = 4.3$, $P = 0.12$, $n = 32$, SNK $P = 0.15$). Parturition rate was higher following moderate oak production (0% vs. 17%, $X^2 = 4.4$, $P = 0.11$, $n = 32$). When non-reproductive bears >4 years old were examined, neither natality nor parturition rate varied significantly by oak production during the previous fall (KW $P \geq 0.77$, $X^2 P = 0.91$). Within all categories of females, neither natality nor parturition rate was positively associated with juniper, pinyon, or softmast production during the previous year.

In years following oak failures, natality was lowest when the failure was preceded by poor oak production, among all females and among eligible reproductive females (KW $P \leq 0.09$, SNK $P = 0.05$). When the failure was preceded by moderate or good oak production, 73% of eligible reproductive females produced cubs. However, none produced cubs when the failure was preceded by a poor oak crop ($X^2 = 10.0$, $df = 2$, $P = 0.007$, $n = 19$). This association was possibly observed for juniper production. During 1993, no juniper survey was completed on the SSA. However, scat analysis and bear weight data indicated juniper production was relatively low. If we assume a juniper failure, or even a poor juniper crop occurred in that year, then natality was positively associated with juniper production during the fall 2 years previous. However, the low oak and juniper production, prior to oak failure, occurred simultaneously, therefore it was not possible to ascertain which genera exerted more of an influence on natality.

Litter Size

A total of 115 litters were handled or observed in dens during 1993 - 2000. Litter size ranged from 1-3 cubs and mean litter size was 1.8 cubs (Table 6-4). Two-cub litters were most common (71%), followed by 1-cub litters (24%).

Three-cub litters were rare, accounting for only 5% of observations. Mean litter size on the NSA (1.9) did not differ ($Z = -1.6$, $P = 0.11$) from that on the SSA (1.7). Observed frequencies of 1-, 2-, and 3-cub litters did not differ by study area ($X^2 = 2.6$, $df = 2$, $P = 0.27$).

Table 6-3. Black bear reproductive parameters associated with variable oak production on 2 New Mexico study areas, 1993-2000. Natality (cubs/female/year) and parturition rates (percent of females with cubs) were analyzed relative to oak production during the previous fall (year-1). Following oak failure, rates were also analyzed relative to fall oak production 2 years previous (year-2). Recruitment rate (yearlings/female/year) and percent of females with yearlings were analyzed relative to fall oak production 2 years previous (year-2). Asterisks indicate distinct subsets differing from other observations within the category, with corresponding P -values provided.

^dFemales were considered eligible for cub production if unaccompanied by yearlings in the den.

First litters were smaller than subsequent litters (1.6 vs. 1.9, $Z = -2.7$, $P = 0.008$, $n = 115$) and frequencies of 1-, 2-, and 3-cub litters also varied ($X^2 = 7.18$, $df = 2$, $P = 0.03$). Specifically, frequency of 1-cub litters was higher among first litters than among subsequent litters. Litter size did not vary by mast production of any species among all litters, first litters, or subsequent litters (KW $P \geq 0.24$).

Table 6-4. Size (range, mean, and relative frequency) of black bear litters observed on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992-2001.

Subsequent litters	86	1 – 3	1.9 [*]	19% [*]	76%	6%

^a Means and frequencies denoted by asterisks were different by litter order ($P < 0.10$).

Cub Survival

Cub survival was documented for 148 individual cubs from 82 litters handled or observed in dens between 1993 and 2000. Overall cub survival rate was 0.55, and observed rates did not differ by study area ($X^2 P = 0.22$) or sex ($X^2 P = 0.30$). Among litters observed, 45% experienced no mortality, 20% experienced partial mortality, and 35% were completely lost. Observed frequencies of litter fate did not differ by study area ($X^2 P = 0.53$).

Cub survival was lower among first litters than subsequent litters (38% vs. 60%, $X^2 = 4.9$, $df = 1$, $P = 0.03$, $n = 148$). Similarly, frequency of whole litter loss was higher among first litters than subsequent litters (57% vs. 30%, $X^2 = 5.7$, $df = 2$, $P = 0.06$, $n = 84$). Based on these findings, cubs were separated into these 2 categories for further analyses.

Among all litters and first litters, cub survival varied positively with juniper and pinyon production during the previous fall ($X^2 P \geq 0.10$), but no differences were found among subsequent litters ($X^2 P \geq 0.34$). The most significant residual corresponded to 100% cub survival ($n = 5$) observed in 1999, following the single most outstanding year of juniper, pinyon, and oak production on the SSA. Cub survival within the cohort born following 1998 was higher than within the combined cohorts born following years of lower production (100% vs. 56%, $X^2 = 3.9$, $df = 1$, $P = 0.07$, $n = 133$). When this cohort was excluded from analyses, cub survival no longer differed by juniper or pinyon production during the previous fall ($X^2 P \geq 0.55$). Instead, cub survival appeared to be weakly associated with oak production during the birth year ($X^2 P \geq 0.14$). The most significant residual was associated with cohorts born during years of oak failure. Their survival rate was lower than the rate observed for cohorts born during years of poor to good oak production (33% vs. 57%, $X^2 = 3.1$, $df = 1$, $P = 0.08$, $n = 136$). The association of low cub survival and oak failure during the birth year was masked when the 1999 cohort was included in analyses. Although this cohort was born during a year of oak failure, it experienced 100% survival, possibly owing to the super abundance of food produced in 1998. Field

observations indicated mast of oak, pinyon, and especially juniper remained available long into the spring and summer of 1999, perhaps compensating for the lack of new production.

To account for the interacting effects of mast production during the previous fall and mast production during the birth year, we produced mast indices combining genera over the 2 periods. Cub survival was most significantly associated with an index of juniper production (during the previous fall) and oak production (during the birth year). For these analyses, we presumed juniper failure on the SSA during 1993 (as described above). Low cub survival was associated with mast failure by oak and juniper; intermediate cub survival was associated with poor to moderate production by oak and/or juniper; and high cub survival was associated with good to excellent production by oak and/or juniper. These patterns in survival were observed among all litters (13% vs. 54% vs. 76%, $X^2 = 9.7$, $df = 2$, $P = 0.008$, $n = 138$) and among subsequent litters (13% vs. 60% vs. 83%, $X^2 = 10.1$, $df = 2$, $P = 0.006$, $n = 108$). Among first litters, no cubs were born in years when both genera failed, however, higher cub survival was associated with good to excellent production (29% vs. 67%, $X^2 = 3.8$, $df = 2$, $P = 0.10$, $n = 30$).

Cub survival varied annually on the SSA within all categories ($X^2 P \leq 0.08$). On the NSA, cub survival did not vary annually within any category ($X^2 P \geq 0.13$). The uniform cub survival observed on the NSA was associated with consistent poor to moderate combined mast production. The variable cub survival on the SSA (13% vs. 63% vs. 76%, $X^2 = 9.9$, $df = 2$, $P = 0.007$, $n = 48$) was positively associated with all 3 levels of mast production. When all observations from the NSA were compared to the SSA observations associated with poor to moderate mast production, no difference was found in the cub survival rate ($P = 0.45$).

Cause of death was rarely documented among cubs, because they were not fitted with radio-transmitters. However, cause of death was documented for 8 cubs, all on the NSA. Two sibling female cubs were killed in August 1993 by an automobile when they attempted to cross a 2-lane highway in Ute Park, adjacent to a campground. These cubs, as well as their mother, frequently obtained food from visitors to the campground and from unsecured garbage containers. In February 1997, a dead female cub was found at the entrance of her den. Her mother and female sibling were hibernating within the den. The position and condition of the carcass indicated she had died at least 6 weeks prior to our discovery and that she had been dragged from the den chamber (probably by her mother). Examination of the carcass indicated a broken pelvis, suggesting she may have died from internal injuries, but cause of the injuries was unknown. This family resided in a part of the study area characterized by very steep slopes adjacent to a 2-lane highway, therefore the injuries may have been sustained in a fall or an automobile collision. Five cubs in 2 litters presumably died from predation, along with their mothers. Although no cub remains were found,

evidence indicated their mothers had been killed by predators, possibly bears. The first incident occurred in May 1995 and the second incident occurred in April 1999.

Recruitment

We estimated recruitment using observations from all females ≥ 5 years old and observations of reproductive females only. Overall recruitment of females ≥ 5 years old was 0.40 yearlings/female/year and 27% of 232 females were accompanied by yearlings in the den. Rates did not differ by study area (MW $P \geq 0.78$, Table 6-2). Recruitment of previously reproductive females was 0.53 yearlings/female/year and percent of females with yearlings was 35% ($n = 175$). These rates did not differ by study area either (MW $P \geq 0.79$).

Within both categories, recruitment was positively associated with fall oak production 2 years previous (KW $P \leq 0.09$, SNK $P \leq 0.10$). Specifically, recruitment was lower 2 years after oak failures than all other years (Table 6-3). Percent of females with yearling also was lower 2 years after oak failures than all other years ($P \leq 0.003$). Neither rate differed relative to poor, moderate, or good oak production 2 years previous ($P \geq 0.43$), nor did they differ by production of juniper, pinyon, or softmast production 2 years prior ($P \geq 0.49$).

Litter Interval

We documented 65 complete litter intervals and 7 incomplete intervals known to be at least 3 years, occurring between 1992 and 2001 (Table 6-5). Incomplete intervals ranged from 3-5 years. However 3 of the 7 incomplete intervals (two 3-year intervals and one 5-year interval) were documented for bears believed to have reached reproductive senescence at 16, 24, and 25 years of age, respectively. Because it was likely these bears would not complete the intervals, these 3 observations were excluded from analyses. In fact, the diseased 16-year-old female did not survive to complete her interval.

Observed litter interval ranged from 1-3 years. One-year intervals occurred when entire litters were lost and bears bred again. Two- and 3-year intervals occurred both when litters were lost and cubs survived, but 3-year intervals included an additional year when the bear failed to produce a litter. Mean litter interval was 1.8 years and it was slightly lower on the NSA than the SSA (1.7 vs. 1.9, $Z = -1.7$, $P = 0.09$, $n = 69$). However, relative frequencies of 1-, 2-, and 3-year intervals were not different between study areas ($X^2 P = 0.15$). Unsuccessful intervals (when entire litters were lost) ranged from 1-3 years with a mean of 1.3 years ($n = 27$). For unsuccessful intervals, neither mean interval nor frequencies of 1-, 2-, and 3-year intervals differed by study area ($X^2 P > 0.44$). Successful intervals (when some or all cubs survived) ranged from 2-3 years with a mean of 2.1 years ($n = 42$). Among successful intervals, frequency

of 3-year intervals was lower on the NSA ($X^2 P = 0.07$), resulting in a lower mean successful interval (2.0 vs. 2.2, $Z = -1.9$, $P = 0.05$).

Table 6-5. Ranges, means, and relative frequencies of black bear litter intervals observed on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992-2001.

Interval type/Area	n	Range (years)	Mean ^a (years)	Relative frequency ^a		
				1-year	2-year	3-year

^a Means and frequencies denoted by asterisks were different by study area ($X^2 P < 0.10$).

Within unsuccessful 2- and 3-year intervals, and within successful 3-year intervals, bears failed to produce cubs at 1 or 2 reproductive opportunities. We observed 14 failed reproductive opportunities, and 71% coincided with oak failures during the previous fall, while 29% coincided with poor to good oak production. Conversely, within 1-year intervals and successful 2-year intervals, bears reproduced at the first reproductive opportunity. We observed 52 successful reproductive opportunities, and only 14% coincided with oak failures, while 84% coincided with poor to good oak production. These observed ratios of failed to successful opportunities varied by oak production ($X^2 = 19.8$, $df = 3$, $P < 0.001$, $n = 66$).

DISCUSSION

The influence of mast production on age of first production of cubs was not entirely clear. Mean age of first litter appeared to increase in years following oak failure. However, production of first litters did not appear to decline, except among 4-year-old bears. This result was possibly due to the small sample size of previously non-reproductive bears aged >4 years observed during years following oak failure. Among females that had produced multiple litters, a higher frequency of skipped reproductive opportunities occurred following oak failure. Therefore, it would be expected that reproduction of potential first litters would also decline. However, production of first litters may not be determined solely by mast production during the previous year. Instead, a bear's ability to produce her

first litter may be influenced by mast production throughout her developing years. Noyce and Garshelis (1994) postulated age at birth of first litter may be more closely tied to cub growth rates and hence the condition of the mother. The more important influence of mast production may be the onset of first estrus. Of 3-year-old females handled between May and September ($n = 18$), only 11% showed signs of estrus, indicating most 4-year-old bears would not reproduce regardless of mast abundance. Even among non-reproductive bears aged 4-6 ($n = 14$), only 43% handled during the mating season appeared to be in estrus.

The influence of oak production, especially acorn failures, on bear reproductive success appeared to be strong. Natality, and subsequently recruitment, was reduced by more than 50% following years of oak failure. Rates were reduced to zero when oak failure was preceded by poor oak production. Availability of hard mast has been tied to reproductive success in several regions (Eiler et al. 1989, Elowe and Dodge 1989, McLaughlin et al. 1994). Neither natality nor recruitment varied following poor, moderate, or even good oak production. Following poor to good production, 94% of eligible reproductively experienced females produced cubs, and no increase in litter size was observed when oak production was high. This suggests only a minimum threshold of high quality food is needed for successful reproduction.

Juniper production possibly had a secondary effect on natality, when oak production failed. Natality rates were zero when oak failure was preceded by poor juniper production. However this poor juniper production coincided with poor oak production, making it impossible to ascertain which genera may have exerted the greater influence on natality. Given the primary effect oak had on reproductive success, it is probable that oak also exerted the greater secondary effect.

Juniper production probably had more of an impact on cub survival than natality. From our observations, juniper berries began to ripen from September to October and remained on the tree through late fall. Berries began to drop during winter and early spring. We observed consumption of significant quantities of juniper berries by bears during fall, spring, and summer (unpublished data). Therefore, more than any other mast genera, juniper could continue to affect the nutritional condition of bears and their cubs long after emergence from the den. Comparing study areas, consumption of juniper berries appeared to be related to production. Juniper production failed each year on the NSA, and only limited consumption of juniper berries was observed, primarily during late fall. The lack of this important spring food, combined with no occurrence of good or excellent fall oak production, resulted in consistent, but low cub survival on the NSA. On the contrary, juniper production varied greatly on the SSA, with crops ranging from failure to excellent. Juniper berries were a significant food item in the spring and summer diets of bears on this area (see Chapter 5). The variable cub survival observed on the SSA was associated with varied levels of juniper and oak production.

No positive association was found between pinyon production and reproductive success. On each study area, pinyon production was better than poor during only 1 year. Unfortunately, on the SSA, the moderate pinyon crop coincided with a good oak crop and an excellent juniper crop in 1998. These simultaneous events did not allow us to assess the effect of pinyon alone on reproductive success. On the NSA, moderate pinyon production occurred in 1993, when both oak and juniper production failed. Nonetheless, natality and recruitment was zero following this production, indicating a moderate supply of pinyon nuts did not compensate for the lack of acorn production. This result may be due to the timing of availability. Pinyon cones mature and open approximately 6 to 8 weeks after the ripening of acorns, possibly limiting the foraging opportunities of bears readying for hibernation. More study is needed to determine the influence of pinyon production on bear reproduction, especially in the absence of other foods.

Production of chokecherries and gooseberries did not appear to influence reproductive success. Compared to the other species surveyed, these soft mast species were more limited in distribution, and were probably available to only a fraction of the bear population. Analyses of foraging habits indicated these species also accounted for <10% of scat volume during the fall (see Chapter 5).

In their study comparing body condition to reproductive success, Noyce and Garshelis (1994) concluded black bears respond to declining nutrition by modifying reproductive performance in the following sequence: (1) litter size, (2) age of primiparity, (3) cub survival, and (4) litter frequency. Our analyses indicated the sequence may be exactly opposite in New Mexico. The greatest influence of mast failure on bears in New Mexico appeared to be a reduction in the number of females producing litters, hence an increase in litter interval. Second, cub survival appeared to decline associated with mast availability. Third, mast failure was associated with a decrease in the percent of bears producing first litters and a resulting increase in the age of primiparity. Litter size did not appear to be associated with availability of mast, among first litters or subsequent litters.

MANAGEMENT IMPLICATIONS

Documenting annual mast production, particularly occurrence and frequency of mast failures, may be an effective tool for monitoring black bear reproductive success in New Mexico. Continuation of the statewide mast surveys, as conducted by NMDGF officers during 1999-2000 (see Chapter 5), will provide valuable data for all regions of bear habitat. These data will be useful for analyzing population trend and interpreting harvest data with the bear population model.

Chapter 7

SURVIVAL RATES AND CAUSES OF MORTALITY

As in many states, the primary foundation for black bear management in New Mexico is information obtained from hunter-killed bears. Fluctuations in the sex and age composition of kills are seen as signals of changing population trends. However, trends in kill data can sometimes be misleading (Garshelis 1991). Therefore, interpretation of kill data is often aided by supporting information about bear population characteristics, especially survival rates, and associated cause-specific mortality rates.

We investigated black bear survival on 2 New Mexico study areas. To better understand the effects of hunting on black bears, a hunting closure was instituted on 1 study area that remained in effect from 1992-1997. Our objective was to document survival and cause-specific mortality rates by sex and age category.

METHODS

We estimated adult (≥ 5 years old), subadult (2-4 years old), and yearling (1 year old) survival rates using data from bears equipped with radio-transmitters. We monitored radio-collared bears from fixed-wing aircraft on a 14-day schedule during the active season (weather permitting). Radio-collars were constructed to emit a "mortality" signal when they remained stationary for more than 2 hours. We ground-tracked all collars emitting a mortality signal to determine whether the signal was a mortality or a dropped collar. We determined approximate date and cause of mortality (when possible).

Hunting mortalities of marked bears were recorded through the New Mexico Department of Game and Fish (NMDGF) mandatory pelt tag program. Personnel of the Colorado Division of Wildlife (CDOW) and the Arizona Department of Game and Fish (ADGF) also reported hunting mortalities. Depredation mortalities and relocations of marked bears were reported by the NMDGF and the CDOW.

Survival rates were calculated using the staggered entry method (Pollock et al. 1989). Rates were estimated separately for each study area by year, within 26 quarter-monthly intervals from May 1 – November 15. Mortality rates for specific causes of death were calculated as $1 - \text{survival rate}$ estimated with deaths from other causes treated as censors. Annual rates over 1993-1999 were averaged with years weighted equally; annual confidence intervals were pooled (N.S. Urquhart, personal communication.)

We used data from all bears with working transmitters monitored for ≥ 1 day during the active season. Bears whose signals were not heard for periods

exceeding 45 days were censored from analyses beginning on the last day of contact. If contact was re-established, bears re-entered the analyses on the day the first signal was heard. If contact was not re-established, bears did not re-enter the analysis.

Radio-telemetry contact was permanently lost for numerous bears during the study period. Some signal loss was probably attributable to premature transmitter failure, transmitter battery expiration, or long-range movements made by bears. However, we suspect other signal loss was due to deliberate destruction of transmitters following human-caused mortality. Signal loss also may have been due to transmitter damage caused by predation. To account for these possibilities in our survival estimates, we identified a portion of the missing bears as possible mortalities.

Assignment of potential mortality for each bear was based on transmitter type, expected battery life left on its transmitter, known failure rate for that transmitter type, and information on subsequent recapture, observation, or mortality. Signal loss was attributed to battery expiration if it occurred at $\geq 70\%$ of battery life. Signal loss was attributed to known failure if transmitters were recovered or observed not functioning or not functioning properly (timer failure of eartag transmitters). Signal loss was attributed to possible signal failure when bears were later captured or killed by hunters not wearing transmitters. Signal loss was attributed to possible damage or weak signal if temporary signal loss occurred ≥ 3 times or if signal loss occurred during the time the bear was denning. Signal loss not attributed to any of these causes was considered possible mortalities. We also reclassified 1 handling mortality as a possible natural mortality due to the poor condition of the bear. Possible survival rates were then calculated including known and suspected mortalities.

RESULTS

Possible Mortalities from Signal Loss

Known and possible failure rates were only 1% and 2% for Telonics and Ursus Technologies (UT) radio-collars, respectively (Table 7-1). However, known failure rate for the Advanced Telemetry Systems (ATS) eartag transmitters was 13%. Due to this high rate of known failure among ATS transmitters, and an even higher number of unexplained signal losses (32%), no missing bears wearing ATS eartags were considered possible mortalities. Eight missing bears wearing Telonics or UT radio-collars were considered possible mortalities due to unexplained signal loss.

Known and Possible Survival Rates

Observed adult female survival rates were very similar for the 2 study areas and were above 90% (Table 7-2). Most mortality of adult females was

human-caused, including hunter kills, depredation kills, and illegal kills (Table 7-3). Surprisingly, female hunting mortality rates were fairly similar for the 2 study areas, despite the hunting closure from 1992-1997 on the NSA. Of 4 adult female bears killed by hunters on the NSA, 1 (25%) was taken after the closure was lifted, 2 (50%) were known to be taken outside of the closure area, and 1 (25%) was reported as taken outside of the hunting closure area, however examination of her movements suggest this may not have been true. Depredation mortalities ($n = 2$) were observed only on the NSA, while illegal kills ($n = 2$) were observed only on the SSA. The 2 illegal kills occurred during the hunting season but no carcasses were found (only cut collars), therefore they may have been unreported legal kills. Of 4 mortalities of unknown cause, 3 (75%) occurred during the hunting season and may have been associated with hunting. However, we found no evidence confirming this due to the condition of the carcasses. The other mortality of unknown cause occurred during August. Despite finding an almost intact carcass, we could not identify the cause of death, but it did not appear to be human-caused.

Table 7-1 . Signal loss from radio-telemetry transmitters fitted on black bears on the Northern Study Area and Southern Study Area, New Mexico, 1992-1999.

	Telonics Radio- Collars	UT Radio- Collars	ATS Eartag Transmitters
Transmitters Used	287	55	38
Total Signal Loss	20 (7%)	9 (16%)	24 (63%)
Known or Probable Battery Expiration	9 (3%)	4 (7%)	7 (18%)
Known Failures	1 (0.3%)	1 (2%)	5 (13%)
Possible Failures with Known Fate	4 (1%)	0	0
Possible Damage or Weak Signal	0	2 (4%)	0
Unexplained Losses	6 (2%)	2 (4%)	12 (32%)

Two known natural mortalities occurred on the NSA and both appeared to be predation. Both females killed had new cubs and the predation occurred during spring. Evidence for the first mortality indicated the bear was killed in a struggle with another bear. Evidence for the second mortality was not conclusive, but bear sign in the area suggested the predator may have been a bear. A possible mortality was observed on the NSA and involved an adult female with a severe case of sarcoptic mange. Her mortality was actually a result of our handling in the den. However she was extremely emaciated and essentially blind (from callousing over her eyes), and we suspect she would not have survived through spring.

Known and possible survival rates of subadult females also were similar between study areas. Known survival rates were very similar to adult females; however possible rates appeared to be somewhat lower. Most mortality of

subadult females also was human-caused. Again, hunting mortality rates were fairly similar for the 2 study areas, despite the hunting closure. The single subadult female killed by a hunter on the NSA was reported as taken outside of the hunting closure area, however examination of her movements suggest this may not have been true. Again, depredation mortality ($n = 1$) was observed only on the NSA. The 2 mortalities of unknown cause were observed on the SSA. Although no cause of death could be identified, timing and locations of these mortalities did not suggest they were human-caused.

Table 7-2. Observed survival rates and 95% confidence intervals (in parenthesis) of adult (≥ 5 years old), subadult (2-4 years old), and yearling (1 year old) black bears monitored on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993-1999. Rates were obtained using the staggered entry method. Known rates included documented mortalities, while possible rates included known and suspected mortalities. Sample size is reported in bear-years.

Unexplained signal loss occurred for 3 subadult females, 2 on the NSA and 1 on the SSA, and these losses were identified as possible illegal kills. Two (67%) signals were last heard just before the start of hunting seasons, suggesting bears may have been unreported legal kills.

Observed yearling female survival was lower on the NSA than the SSA, but sample sizes were relatively small. On the NSA, all mortalities ($n = 3$) were of natural causes. One bear appeared to have died of starvation after emerging from the den with low weight. One bear appeared to have been preyed on by a mountain lion. One bear may have been preyed on by a bear. However, no clear evidence of predation was found, other than the fact the carcass was fed on

by a bear. It should be noted the 2 mortalities attributed to predation might have been affected by our research activities. During 1994, larger collars were put on young bears and the burden of these large collars may have affected their survival. Since that time, we have used smaller, expandable collars on yearling and subadult bears in an effort to reduce our influence on survival. On the SSA, one mortality of a subadult female was attributed to illegal kill. This mortality occurred during the hunting season but no carcass was found (only a cut collar); therefore it may have been an unreported legal kill.

Table 7-3. Cause-specific mortality rates of adult (≥ 5 years old), subadult (2-4 years old), and yearling (1 year old) black bears monitored on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993-1999. Rates were obtained using the staggered entry method. Known rates included documented mortalities, while possible rates included known and suspected mortalities.

Known adult male survival rates were very similar for the 2 study areas and were above 90%. However, including possible mortalities, the possible

survival rate dropped to 82% on the SSA. Specific causes of death were different between study areas, however all were human-caused. Mortality sources for adult males included hunting, illegal kill, depredation kill, and automobile collision. As expected, male hunting mortality was lower on the NSA than on the SSA, and the single adult male killed by hunters on the NSA was taken after the hunting closure was lifted. One adult male captured on the SSA was killed in Arizona during their hunting season. On the NSA, 2 adult males were illegally killed outside of the hunting season. Radio-collars of these males were disposed of in Eagle Nest Lake and in the Cimarron River. On the NSA, 2 adult males appeared to have died from collisions with automobiles on U. S. Highway 64 in Cimarron Canyon.

Unexplained signal loss occurred for 3 adult males on the SSA, and these losses were identified as possible illegal kills. None of these possible mortalities occurred during the hunting season, suggesting they were not unreported legal kills. Although these mortalities cannot be verified, the documented occurrence of illegal kills of adult males on the NSA, coupled with documented occurrence of illegal kills of other bears on the SSA, indicate a high probability for illegal kill of adult males on the SSA. Inclusion of these possible mortalities doubled the mortality rate of males on the SSA.

Observed survival rates of subadult males were high on both study areas, and no hunting mortality was documented. The single documented mortality was a depredation kill following an incident on Philmont Scout Ranch when the bear entered a camp and scratched a scout inside a tent.

Unexplained signal loss occurred for 1 subadult male on the SSA, and this loss was also identified as a possible illegal kill. This possible mortality occurred during the bear hunting season, suggesting it may also have been an unreported legal kill.

Observed male yearling survival appeared lower on the SSA than the NSA. The single mortality documented on the NSA was an illegal kill during the bear season (the carcass was found). On the SSA, 1 yearling male mortality was due to predation by another bear. Cause of death was not known for the other 2 mortalities, but locations and dates did not suggest they were human-caused.

One SSA yearling bear never left the den following our den investigation. We suspect he may have died as a result of our handling, therefore this bear was censored in analysis of the known survival rates. However, the bear may have also died from natural causes, therefore it was included in analysis of possible mortality. Inclusion of this mortality increased the observed total mortality rate on the SSA from 18% to 24%. Unexplained signal loss occurred for 1 yearling male on the NSA, and this loss was attributed to an unknown cause. The signal was lost from this bear only weeks out of the den, and it was unlikely the possible death was human-caused.

DISCUSSION

Although not statistically distinct, survival rates appeared to differ among sex-age categories during this study. Among adult and subadult bears of both sexes, human-caused mortality was most common. Among yearling bears, most mortality was from natural causes, but human-caused mortality was also observed. Mortality from hunting was lower on the NSA and this difference was probably attributable to the hunting closure in effect from 1992-1997. However, even during the years of closure, hunting mortality was observed on the NSA. Most mortalities occurred outside of the closed area, indicating it was not large enough to allow complete protection for resident bears. However, we suspect 2 of the hunt mortalities occurred within the area of the hunt closure, indicating a possible source of illegal activity. Other sources of human-caused mortality included illegal kill, depredation kill, and automobile collisions. These sources of mortality were substantial, especially on the NSA, where they accounted for as much as 10% mortality.

Within the Southwest, observed adult female survival rates from this study were similar to those reported in Colorado (0.96: Beck 1991) and Mexico (0.94, Doan-Crider and Hellgren 1996), but higher than those reported in Arizona (0.85: LeCount 1990). Observed adult male survival rates were slightly higher than those reported in Arizona (0.85: LeCount 1990) and substantially higher than those reported in Colorado (0.70: Beck 1991).

The lack of documented hunting mortality among subadult males was surprising, given the substantial proportion of subadult males observed in hunter harvests. Relative to adults, and even subadult females, sample sizes were low for subadult males; therefore these results should be interpreted with caution. Our observed subadult male survival was higher than that observed in Colorado (0.76: Beck 1991), but our observed subadult female survival was similar to Colorado (0.94: Beck 1991).

Yearling survival rates appeared lower than those of adults and subadults, however much of the documented mortality was due to natural causes. Due to the small sample sizes associated with this ageclass, these results should also be interpreted with caution. Yearling survival rate was lower than the rate reported for Colorado (0.94: Beck 1991).

MANAGEMENT IMPLICATIONS

Among adult and subadult bears, most mortality was human-caused. In addition to hunting, illegal kills and depredation kills were significant sources of mortality for these bears. Illegal kills were documented on both study areas, and many of the unexplained losses were probably due to illegal kills followed by destruction of the transmitters. We were unable to verify any of these possible

mortalities, therefore these possible rates should be viewed as maximum rates. Depredation mortality was only documented on the NSA. The proximity of the NSA to several towns, as well as the inclusion of Philmont Scout Ranch within its boundaries, increased the likelihood of bear-human interactions.

It is important to recognize that there was no legal hunting on the NSA during 1992 through 1997. Therefore the hunting mortality rates observed may not reflect actual mortality of bears from hunting in northern New Mexico. The possibility of total mortality exceeding the rates we observed must be considered when interpreting harvest data and output from the population model.

CHAPTER 8

DENNING CHRONOLOGY AND DEN SITE SELECTION

As omnivores, New Mexico black bears are faced with reduced foraging opportunities during winter, primarily due to a lack of new plant growth, desiccation of existing plant matter, and accumulation of snow. Like bears throughout most of their range, New Mexico bears respond to this limited food supply by hibernating. Use of dens or shelters during this extended period of immobility provides both security from predators and protection from extreme weather (Nelson and Beck 1984, Beck 1991).

Timing of den entry and emergence is widely variable among populations and between individuals within a population. Typically, female bears enter dens earlier and emerge from dens later than male bears across North America (Tietje and Ruff 1980, Beecham et al. 1983, LeCount 1983, O'Pezio et al. 1983, Beck 1991, Schooley et al. 1994, Weaver and Pelton 1994, Oli et al. 1997). The prolonged denning period of females is usually most pronounced for adults giving birth during that period. Knowledge of the denning chronology of New Mexico black bears may facilitate more effective management of hunting. In many states and provinces, patterns of differential denning chronology afford wildlife managers an opportunity to regulate the demographic composition of bear harvests (Troyer 1961, Lindzey 1981). In addition, interpretation of hunter-kill data also is enhanced with an understanding of the denning behavior of populations (Alt 1977, O'Pezio et al. 1983).

Knowledge of den site characteristics is also valuable. Energetic properties and level of security of the physical site of hibernation may play a role in the success of bear populations. Where quality den sites are limited, forest management practices can be adjusted to increase their availability (Weaver and Pelton 1994, Oli et al. 1997).

Our objectives were to (1) document den entrance and emergence dates by sex-age category and study area, and (2) document den site characteristics by sex and study area.

METHODS

Denning Chronology

We estimated dates of den entrance and den emergence using aerial telemetry data. During appropriate months (1 October–15 December and 15 March–30 May), we intensified our flight schedule in an effort to locate each radio-collared bear once per 7-10 days (weather permitting). We did not attempt to determine exact dates of den entry or emergence by observation because of the possibility of disturbance.

Studies have shown bears often concentrate their movements around den sites days or weeks before den entry, and bears often remain in the den vicinity after emergence in the spring (Lindzey and Meslow 1976, LeCount 1980, Tietje and Ruff 1980, Beecham et al. 1983, Kolenosky and Strathearn 1987). Our observed telemetry error prevented us from distinguishing very small movements associated with a specific den location. Therefore, we defined denning dates as those when bears were in the den vicinity, not dates of actual movement into or out of the den cavity.

For each consecutive location, we assigned active or denned status based on its proximity to the previous location or its proximity to the actual den site (documented during a den visit). Other relevant information, particularly observer notes and "mortality" signal status, also were considered. Denning occurred when a bear was found in the "same" location during 2 or more consecutive flights, or when a bear was located at its documented den site. Locations were considered the same if they were within the median aerial telemetry error radius of 505 m. Bears were considered active the first time they were located more than 505 m from the den site in the spring.

We defined the fall den entry date as the midpoint between the last active location and the first denned location. Similarly, we defined the spring den emergence date as the midpoint between the last denned location and the first active location (O'Pezio et al 1983). For den entry, we limited our analyses to those observations when the period between relevant locations was ≤ 15 days; and for den emergence, we limited the period to ≤ 20 days. These criteria allowed us to use approximately 50% of our data. To eliminate the potential bias of our research activities, we excluded den emergence observations when the first active location occurred following our den visit.

We used analysis of variance (ANOVA) to determine differences in den chronology among the following sex-age categories: pregnant females (with cubs at den emergence), females with yearlings, other females, adult males, and subadult males. We used t-tests to determine differences within distinct categories between study areas.

We determined total denning period for bears with entrance and emergence dates as defined above. Differences in denning period was tested among sex-age categories using ANOVA and tested between study areas using *t*-tests. All analyses were performed using SPSS software (Chicago, Illinois); where appropriate because of variance differences, degrees of freedom are expressed as decimals.

Den Characteristics

We documented den characteristics, site features, and habitat variables during all visits to winter dens. Den type, number of entrances, types of bedding material, and prior use were recorded. Prior use was known when previous visits to the same den were made. Prior use was judged probable based on characteristics such as vegetation growth on the dirt berm of an excavated den, soil compaction of the berm, and old claw marks on hollow trees. We recorded elevation, topographic position, slope, and aspect of each den site. Habitat type was assigned following Brown (1982). We estimated canopy cover above 0.9 m (3 ft), and ground cover at 0-0.3 m (0-1 ft) and 0.3-0.9 m (1-3 ft) in the following categories: 1-5%, 6-25%, 26-50%, 51-75%, 76-100%. For analysis of aspect at the den site, aspect was classified into 9 categories: N, NE, E, SE, S, SW, W, NW, and flat (no aspect).

RESULTS

Denning Chronology

Among all bears on both study areas, observed den entrance dates ranged from 25 September-7 February ($n = 179$). Range of den entrance dates differed among sex-age categories and between study areas (Table 8-1). Among males, the first observed den entrance date was 18 October, while the latest was 29 December. Among females, the first observed den entrance date was 25 September, while the latest was 7 February. Among both sexes, the majority of bears entered dens between mid October and mid November (Figure 8-1).

Table 8.1. Ranges and means of black bear den entrance dates, by sex-age category, observed on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992–1999.

Area	Sex-age Category	<i>n</i>	Earliest	Latest	Mean
NSA	Pregnant females	33	25 September	21 November	26 October
	Females with yearlings	18	12 October	8 December	3 November
	Other females	27	7 October	28 November	2 November
	Adult males	27	18 October	21 November	3 November
	Subadult males	13	19 October	24 November	2 November
SSA	Pregnant females	10	29 October	15 November	11 November
	Females with yearlings	7	3 November	27 January	28 November
	Other females	31	20 October	7 February	8 November
	Adult males	8	29 October	29 December	18 November
	Subadult males	5	2 November	10 December	11 November

—□— Pregnant females (n = 33) —▲— Other females and males (n = 85)

—□— Pregnant females (n = 10) —▲— Other females and males (n = 51)

Figure 8-1. Cumulative percent of black bears that entered dens, by week, on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992-1999.

Mean den entrance date differed among the 5 sex-age categories ($F = 2.5$; $df = 4, 174$; $P = 0.05$), but subsets were not distinct. When observations were divided into 3 categories (pregnant females; females with yearlings; other females and males), 2 distinct subsets were identified (SNK, $P = 0.05$). Mean entrance date of pregnant females was 29 October, while that of all other bears was 6 November. Comparison of 95% confidence intervals indicated pregnant females entered dens approximately 1-15 days earlier than all other bears.

Within both groups, mean den entrance date also differed between study areas. Pregnant females entered dens approximately 4-25 days earlier on the NSA (26 October vs. 10 November, $t = -4.3$, $df = 27.9$, $P < 0.001$). Other bears entered dens about 2-19 days earlier on the NSA (3 November vs. 13 November, $t = -3.0$, $df = 68.3$, $P = 0.003$).

On the SSA, mean den entry date differed by oak production for the group of other females and subadult males ($F = 3.4$, $df = 2, 40$, $P = 0.04$, $n = 42$) and for pregnant females ($t = -4.1$, $df = 2.0$, $P = 0.05$, $n = 9$). Other females and subadult males entered dens later during the years of good oak production than all other years (30 November vs. 8 November, SNK $P = 0.05$). Pregnant females entered dens later during years of good oak production than during years of poor production (15 November vs. 31 October). Mean den entry date did not differ significantly by oak production on the NSA.

Among all bears on both study areas, observed den emergence dates ranged from 21 March-5 June ($n = 177$). Range of emergence dates was similar for males and females (Table 8-2). Among males, the earliest observed date was 21 March, while the latest was 20 May. Among females, the first observed den emergence date also was 21 March, while the latest was 5 June. Among both sexes, the majority of bears emerged from dens during April (Figure 8-2).

Table 8.2. Ranges and means of black bear den emergence dates, by sex-age category, observed on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993–1999.

Area	Sex-age Category	<i>n</i>	Earliest	Latest	Mean
NSA	Females with cubs	40	9 April	5 Jun	10 May
	Females with yearlings	19	13 April	19 May	4 May
	Other females	31	1 April	23 May	1 May
	Adult males	20	21 March	20 May	21 April
	Subadult males	7	29 March	20 May	30 April
SSA	Females with cubs	10	28 March	29 April	24 April
	Females with yearlings	3	21 March	6 May	15 April
	Other females	28	21 March	31 May	21 April
	Adult males	12	23 March	6 May	14 April
	Subadult males	7	6 April	6 May	24 April

Figure 8-2. Decreasing percent of black bears remaining in dens, by week, on the Northern Study Area (NSA) and southern Study Area (SSA), New Mexico, 1993-1999.

Mean den emergence date differed among the 5 sex-age categories ($F = 9.8$; $df = 4, 172$; $P < 0.001$). Using a SNK test, females with yearlings, other females, and subadult males constituted a homogenous subset. When this combined group was compared to females with cubs and adult males, all 3 categories were different (SNK, $P = 0.05$). Adult males emerged earliest with a mean date of 18 April. The mean date for combined group was 28 April. Females with cubs emerged the latest, with a mean date of 7 May.

Comparing these groups between study areas, we observed some differences in mean date. Among the combined group of other females and subadult males, bears emerged about 2-19 days earlier on the SSA (21 April vs. 2 May, $t = 3.8$, $df = 93$, $P < 0.001$). Females with cubs emerged from dens about 6-27 days earlier on the SSA (24 April vs. 10 May, $t = 4.4$, $df = 48$, $P < 0.001$). Mean date did not differ between areas for adult males (19 April, $t = 1.6$, $df = 32$, $P = 0.12$).

Total denning period for 83 individuals varied significantly among the 5 sex-age categories ($F = 2.6$; $df = 4, 78$; $P = 0.04$), however homogenous subsets overlapped (Table 8-3). Denning period of adult males was different from all other bears combined. Denning period of adult females with cubs also differed from all other bears combined. Combining all sex-age categories, mean denning period was shorter on the SSA than the NSA (165.6 vs. 178.0 days, $t = 2.4$, $df = 81$, $P = 0.02$).

Table 8.3. Ranges and means of black bear total denning period (days), by sex-age category, observed on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993–1999.

Area	Sex-age Category	<i>n</i>	Minimum	Maximum	Mean
NSA	Females with cubs	16	165	229	187.1
	Females with yearlings	10	145	201	172.4
	Other females	13	145	216	173.8
	Adult males	8	155	203	173.8
	Subadult males	3	162	197	178.0
SSA	Females with cubs	3	171	181	174.3
	Females with yearlings	2	151	163	157.0
	Other females	19	42	198	170.6
	Adult males	6	98	170	142.7
	Subadult males	3	171	185	180.3

Den Characteristics

Over 64% of 390 dens visited during 1993-2000 were associated with rock structure, including excavations under rock (35%) and natural rock cavities (30%). Den types associated with tree structure were used to a lesser degree (a

total of 31%), with 20% of dens excavated under trees and 11% in natural tree cavities.

Use of den types differed by sex and study area ($X^2 = 96.1$, $df = 18$, $P < 0.001$, $n = 387$). Females and males on the NSA used dens excavated under rocks more than bears on the SSA (Table 8-4). Females on the SSA used tree cavity dens and dens excavated under trees more than any other group. Males on the SSA used rock cavity dens more than any other group.

Table 8-4. Relative use of den types by female and male bears on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993-2000.

Den type	NSA		SSA	
	Females ($n = 173$)	Males ($n = 53$)	Females ($n = 132$)	Males ($n = 29$)
Rock cavity	0.25	0.32	0.24	0.69
Tree cavity	0.06	0	0.24	0
Excavated under rock	0.43	0.60	0.17	0.24
Excavated under tree	0.21	0.08	0.27	0.03
Excavated into ground	0.03	0	0.06	0.03
Ground nest	0.01	0	0.01	0
Other	0.01	0	0	0

Bears denned in a variety of habitats (Table 8-5). The most commonly used habitats were mixed conifer forests (45%), pinyon-juniper woodlands (21%), spruce-fir forests (13%), ponderosa pine forests (9%), and oak shrublands (8%). Other den-site habitats included aspen forests (3%), bristlecone and limber pine forests (2%), desert shrubland (<1%), and subalpine-plains grassland (<1%). On each study area, bears denned most frequently in mixed conifer habitat. Bears of the NSA used pinyon-juniper habitat secondarily, while SSA bears used pinyon-juniper and oak habitats secondarily.

Denning habitat differed by sex and study area ($X^2 = 63.5$, $df = 24$, $P < 0.001$, $n = 380$). Males denned in scrub oak habitat more frequently than females on both study areas (Table 8-5). Females on the NSA denned in spruce-fir habitat more frequently than other groups and SSA females denned in mixed conifer habitat more frequently than other groups. Use of pinyon-juniper and ponderosa habitats did not differ between sexes on either study area.

Certain den types were more closely associated with specific habitats. Over 95% of tree cavity dens were located in mixed conifer or spruce-fir habitat ($n = 42$), with the vast majority (83.3%) located in mixed conifer habitat. Over 82% of dens associated with tree structure were located in mixed conifer or spruce-fir habitats ($n = 120$). All dens located in scrub oak habitat ($n = 28$) and

88% of dens located in pinyon-juniper habitat ($n = 69$) were rock cavity dens or dens excavated under rocks.

Table 8-5. Relative use of habitat types for denning by female and male bears on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993-2000.

Habitat type	NSA		SSA	
	Females ($n = 174$)	Males ($n = 50$)	Females ($n = 126$)	Males ($n = 27$)
Grassland	0.01	0	0	0
Oak shrubland	0.01	0.20	0.08	0.26
Pinyon -juniper woodland	0.22	0.24	0.13	0.22
Ponderosa pine forest	0.10	0.06	0.10	0.07
Aspen forest	0.02	0.02	0.02	0.07
Mixed conifer forest	0.41	0.36	0.57	0.33
Spruce-fir forest	0.20	0.10	0.09	0.04
Bristlecone-limber pine forest	0.03	0.02	0	0

Elevation at den sites ranged from 1,636 - 3,576 m (5,400 - 11,800 ft). Elevation differed by study area ($t = 7.5$, $df = 385$, $P < 0.001$, $n = 385$); elevation at NSA den sites averaged 2,657 meters (8,768 feet) whereas SSA den sites averaged 2,427 meters (8,010 feet). Elevation differed by sex on each study area. Males on the NSA denned at lower elevations than females (2,485 vs. 2,706 m, $t = 4.0$, $df = 222$, $P < 0.001$, $n = 224$), as did males on the SSA (2,332 vs. 2,448 m, $t = 2.4$, $df = 159$, $P = 0.02$, $n = 161$).

Aspect at den site differed by sex and study area ($\chi^2 = 51.1$, $df = 24$, $P = 0.001$, $n = 390$) and the significant differences were primarily among females. Female bears on the NSA selected dens with SW aspects more frequently and dens with NW aspects less frequently than other bears. Female bears on the SSA selected dens with NW aspects more frequently and dens with S or SE aspects less frequently than other bears. There was no difference between study areas in use of aspect by male bears ($\chi^2 = 4.7$, $df = 7$, $P = 0.70$, $n = 82$).

Slope at den sites ranged from 0° – 90° and the mean was 28° ($n = 386$). Only 1 den site had a slope of 90° . It was a natural rock cavity den used by a subadult male on the SSA, situated on a sheer cliff face with a narrow path to the entrance. There was no difference in slope at the den site between study areas ($P = 0.173$). However, there was a difference between the sexes, with males using steeper slopes than females (31° vs. 27° , $P = 0.006$).

Bears denned at all categories of topographic position, however few den sites were located on ridge-tops (5%) or bottoms (3%). Most den sites were located at the upper portion of slopes (42%), the mid portion of slopes (37%), or the lower portion of slopes (13%). Bears on the NSA denned most frequently at

mid-slope (43%), while SSA bears denned most frequently on the upper slope (48%).

The number of useable entrances into a den ranged from 1 to 4, but most dens had only 1 entrance (94%, $n = 390$). Twenty-one dens had 2 entrances (5%), 2 dens had 3 entrances (1%), and 1 den had 4 entrances (<1%). Eighteen of 24 (75%) dens with more than 1 entrance were natural rock cavity dens. Only 7% of den entrances were blocked with bedding material ($n = 381$), and this frequency did not differ by study area or sex ($P \leq 0.11$). Snow covered 22% of den entrances ($n = 377$); this frequency did not differ by study area or sex ($P = 0.67$). Snow cover ranged from approximately 15cm to 1.2m. Typically, there was a small hole in the snow (5-15cm diameter) that was kept open by heat generated from within the den.

Bedding material was found in 93% of all bear dens ($n = 360$) and was common to all sex and age categories. Percent of dens with beds was high on both study areas, however SSA females used beds most frequently and NSA females used beds least frequently (98% vs. 89%, $X^2 = 7.5$, $df = 3$, $P = 0.06$, $n = 357$). Common bedding materials found in 351 dens were pine needles (48%), twigs (42%), leaves (39%), and grass (37%). Other materials included conifer boughs, duff, bark, bracken fern (*Pteridium* spp.), yucca (*Yucca* spp.), beargrass (*Nolina microcarpa*), conifer cones, lichen, moss, agave (*Agave* spp.), silktassel (*Garrya* spp.), and remains of rodent midden. An earthen floor, sometimes strewn with stones, characterized dens lacking a bed.

Of 390 dens visited on both study areas, 10% were definitely used in years prior to the visit, and an additional 26% likely were used in years prior to the visit. There was a difference in the frequency of den re-use by study area ($X^2 = 14.8$, $df = 1$, $P < 0.001$, $n = 387$). Definite or probable re-use occurred at 43% of the NSA den sites, but only 24% of the SSA den sites. On the SSA, males denned in sites believed to have been previously used more often than females (38% vs. 21%, $X^2 = 4.0$, $df = 1$, $P = 0.06$, $n = 161$). Rates of probable re-use did not differ by sex on the NSA ($P = 0.27$). Several bears on the NSA were observed to use the same den 2-5 times during the study period. Use of the same den by different individuals also was observed.

DISCUSSION

Johnson and Pelton (1980b) proposed that 2 factors interact to ensure optimal timing of hibernation and denning of black bears. The primary factor is a genetically controlled hormonal response to photoperiod, or day length. This factor is modified by annually variable elements such as weather and food supply. These factors interact to provide the final stimulus to den.

Erickson and Youatt (1961) reported that prolonged feeding delayed denning of captive bears, but when feeding was terminated, denning occurred

promptly. Delayed den entrance by wild black bears has been documented during years of greater fall food availability in Maine (Hugie 1982, Schooley et al. 1994), Alberta (Tietje and Ruff 1980), Tennessee (Johnson and Pelton 1980b), and Idaho (Beecham et al. 1983). In Ontario, bears that fed on acorns, a food with high fat and carbohydrate content (Eagle and Pelton, 1983), denned significantly later than bears not feeding on acorns (Kolenosky and Strathearn 1987). Shorter denning periods observed in mild climates has led to the theory that bears forage until they encounter a decreasing or negative energy return per unit of search effort (Lindzey and Meslow 1976, Johnson and Pelton 1980b).

Timing of den entrance also has been reported to be influenced by various weather factors including snowfall (Jonkel and Cowan 1971), temperature (Johnson and Pelton 1980b, Rogers 1987), and precipitation (Lindzey and Meslow 1976, Johnson and Pelton 1980b). However, Schwartz et al. (1987) and Schooley et al. (1994) reported that variation in den entry was not strongly associated with weather patterns during autumn. Bears have the physical capability to survive brief periods of hostile weather, and onset of hibernation is probably not controlled by changes in weather. Rather, inclement weather typically coincides with decreased food availability, and tends to compound the negative energy return of a dwindling food supply by increasing the foraging effort required to obtain food. In the case of snow cover, food is exponentially more difficult to find and retrieve per unit effort of search.

On average, we observed bears entering dens 1-2 weeks later than usual during a single year of outstanding food production on the SSA. Two females without offspring were observed to delay den entrance until January and February. That year of outstanding mast production also was characterized by mild weather and little snowfall, allowing for increased foraging opportunities. Dates of den entrance were not different among years of oak production ranging from failure to moderate. Overall, our results lend support to the theory of negative energy return and that food availability is the primary proximate cause of black bear den entry. We hypothesize that years of mast failure do not result in earlier den entrance because the endogenous rhythm has not yet prepared bears to den. Weather factors are likely a secondary proximate cause of den entrance.

Smith et al. (1994) summarized denning chronology results of 25 black bear research projects and concluded that populations of more northern latitudes and higher elevations tend to enter dens earlier, remain denned longer, and emerge later. Our data suggest this pattern may exist within New Mexico. Mean entrance dates of the SSA population were very similar to those of central Arizona (LeCount 1983), and were approximately 2 weeks later than those observed on the NSA. Entrance dates of NSA bears were more similar to those of Colorado (Beck 1991) and Idaho (Beecham et al. 1983). Bears inhabiting mountain ranges in New Mexico of lower elevations than our study areas may display this trend to a greater degree. With uniform hunting seasons for black

bears throughout New Mexico, regional differences in denning chronology will likely affect the demographic composition of the harvest and interpretation of population sex and age structure from harvest data.

Differential denning dates among demographic segments of black bear populations has been widely reported in such regions as the Southwest (LeCount 1983, Beck 1991), the Pacific Northwest (Lindzey and Meslow 1976, Schwartz et al. 1987, Smith et al. 1994), the intermountain west (Tietje and Ruff 1980, Beecham et al. 1983), the Northeast (O'Pezio et al. 1983, Schooley et al. 1994), and the Southeast (Johnson and Pelton 1980b, Weaver and Pelton 1994, Oli et al. 1997). Typically, females enter dens earlier than males. Pregnant females enter dens earlier than any other group, and adult males enter dens latest. The reverse sequence is commonly observed at den emergence. Subadult entrance and emergence appears to be more random and has not exhibited the definitive patterns apparent between sex and reproductive groups. Bears of New Mexico exhibited these same demographic variations and fit the overall pattern documented with other research projects. Mean den entrance date for pregnant females was earlier than all other bears on both study areas. The weekly cumulative percentage of pregnant females having entered dens was 5-30% greater than for all other bears on the NSA during peak entrance in October; den entry by pregnant females on the SSA probably was similar but sample size was too small to document this pattern. Den emergence patterns in New Mexico also fit the general pattern of other research findings. Adult male bears on both study areas emerged earliest and females with cubs emerged latest. Mean emergence dates differed by 10-20 days between these groups. The weekly cumulative percentage of adult males that had departed the den vicinity was 20-50% greater than for females with cubs during peak emergence in April and May.

Bears of New Mexico exhibited these same demographic variations and fit the overall pattern documented with other research projects. Mean den entrance date for pregnant females was earlier than all other bears on the NSA and the SSA. Also, the weekly cumulative percentage of pregnant females that had entered the den was 5-30% greater than for all other bears on the NSA during October; den entry by pregnant females on the SSA probably was similar but sample size was too small to assess this pattern. These differences generally agree with other documented populations.

Emergence from dens in New Mexico also fit the general pattern of other research findings. Adult male bears on both study emerged earliest, females with cubs emerged latest; average emergence dates differ by 10 to 20 days between those groups. Also, the weekly cumulative percentage of adult males that had departed the den vicinity was 20-50% greater than for females with cubs during peak emergence in April and May. However this emergence schedule was about 20 days later on the NSA than the SSA. These differences generally agree with other documented populations.

We found that male and female black bears selected different types of den sites and den structure, and that trends were similar between regions in New Mexico. In general, males denned at lower elevations, on steeper slopes, in oak habitats, and in rock dens. Females used dens associated with trees with greater frequency than males and denned at higher elevations, on more moderate slopes, and in spruce-fir and mixed conifer habitats. While some of the variation in the aforementioned den characteristics may be inter-related (primarily site-characteristics), much of the differences that we observed in New Mexico can, in large part, be explained by differing needs of the sexes and the adaptive significance they afford each sex.

Black bears den for periods up to 6 months long and can lose 14-34% of their body weight during the denning period (Hock 1960, Erickson and Youatt 1961, Tietje and Ruff 1980). Females nursing cubs may lose an additional 9% above the 25% that other females lose during denning (Tietje and Ruff 1980). In addition, factors other than metabolic expenditure also influence energy conservation during the denning period. Bears have been documented changing dens within a winter apparently by natural causes (LeCount 1980, Weaver and Pelton 1994). Abandonment of a den site was estimated to cause a doubling of over-winter weight loss (Tietje and Ruff 1980). Considering the intense physiological demands of denning, lactation, and the generally poor forage conditions available to bears upon emergence, the need for den types that favor energy conservation during this period is obvious.

The insulating capacity of snow is well known and of great significance to bears of more northern regions where accumulations are deep enough to cover dens and mid-winter thawing is not frequent (Tietje and Ruff 1980). We found that 22% of dens in New Mexico were covered with snow at our visit date. We did not detect any difference in the frequency with which male and female dens were covered with snow. Interestingly, there also was no difference in frequency of snow-covered dens between study areas even though the NSA was farther north and included areas of higher elevation. Bears on the SSA, particularly females, used NE slopes more frequently which may account for this lack of difference. Female use of higher elevations on both study areas may represent an inclination to use more insulated dens.

Use of tree cavity dens by black bears may result in energetic conservation in regions where snow accumulations are not significant, mid-winter rains occur, or intermittent flooding occurs (Johnson and Pelton 1980b, Weaver and Pelton 1994, Oli et al. 1997). Johnson et al. (1978) simulated winter heat loss of denned black bears and concluded that enclosed tree cavity dens accounted for a 15% energy savings compared to open ground dens. However, Thorkleson and Maxwell (1974) suggested while dens afford protection from conductive, convective, and radiant heat loss, the increased air circulation can greatly reduce their thermal efficiency. Because of its latitudinal position and range of elevations, New Mexico falls somewhere between the typical northern

bear habitats and those with less severe winters. The fact that only 22% of dens were covered with an insulating blanket of snow indicates that thermally insulated dens may have great importance for bears in New Mexico. The need for more thermally efficient dens may be greater for females and younger bears due to their higher surface area to volume ratio. Observed use of tree dens was higher on the SSA, where snow accumulation was more limited. Although male bears have been observed to use hollow trees for denning in other regions (C. Godfrey, pers. commun., 1998), no use of tree cavity dens by males was observed during this study. It is possible that availability of large cavities suitable for adult males is limited in New Mexico.

In addition to energetic conservation, security is another factor of importance related to den type. Predation of denned black bears by wolves (Rogers and Mech 1981), man (Erickson 1964), and other bears (Rogers 1977, Tietje and Ruff 1980, Alt 1984) has been reported. Security of the den site is affected by inaccessibility, defensibility, and cover. Females may seek tree den types because of a greater need for security, due to their smaller size and the vulnerability of cubs. Bears that den in hollow tree cavities above the ground are less accessible to potential predators than those in other den types. During this study, no elevated tree cavity dens were abandoned at our approach, supporting previous contentions that bears denning in trees were less vulnerable to human disturbance than those using ground (Johnson and Pelton 1981, Weaver and Pelton 1994). Den types other than elevated tree cavities appear to be less secure, but similarly inaccessible and defensible to each other. Ninety-four percent of the dens we examined had only 1 entrance. Although lethargic and approachable while denning, bears remain capable of defending themselves. Cover would appear to function for security purposes by reducing the odds that a den could be located, and, as we often found during the research effort, by functioning as an auditory alarm system. Undetected approaches to dens were difficult to achieve in thick scrub oak and mountain mahogany vegetation and/or steep terrain covered with loose rocks.

Craighead and Craighead (1972) suggested grizzly bear use of northern aspects for den sites reduced the likelihood of a flooded den as the result of a mid-winter thaw. Cub mortality from hypothermia and drowning, associated with flooding of dens, has been observed (Alt 1984, Hayes and Pelton 1994, Weaver and Pelton 1994). Although SSA females appeared to favor dens with NW aspects, NSA females tended to avoid this aspect, selecting sites with SW aspects instead. Snowmelt on south-facing slopes was relatively common on both study areas. We observed flooding of a maternal den on the NSA during a den visit in late March. The den was beneath a rock ledge where snow was melting through the roof of the den. The female, her 2 cubs, and all of the bedding material were extremely wet, however the female remained lethargic. Fearing for the survival of the cubs, we dried them, put fresh bedding under them, and attempted to redirect the snowmelt. Fortunately, the bears moved from the den within 2 days after the den visit. It is unknown if the bears would

have moved without our disturbance. On the SSA, females may have selected north-facing slopes to avoid frequent snowmelts that may reduce cub survival; however other factors, such as availability of large tree dens, may have caused them to select these sites.

Relatively high levels of den reuse have been documented in other regions, particularly in western states, such as Colorado (Beck 1991), Idaho (Beecham et al. 1983), and Alaska (Smith et al. 1994). Methodologies used to determine rates of den reuse differed widely among studies, making comparison difficult. Lindzey and Meslow (1976) documented a high degree of den reuse (90% of all bears reused dens) and attributed it to reduced den site availability following logging. Schwartz et al. (1987) documented competition among bears for den sites. The wide variety of den types observed during this study suggested availability of dens was not limiting.

MANAGEMENT IMPLICATIONS

The verified differential in den entry and emergence dates among sex and age groups has application to setting bear hunting seasons to accomplish various objectives. However, den entry and emergence dates are highly variable and generally span a period exceeding 2 months. We observed variation relative to mast production; other factors undoubtedly play a role influencing the timing from year to year. No single timing scenario is appropriate for every use. This information also is valuable for interpreting past and future harvest composition relative to season timing and region. These interpretations are especially important for selecting information to be used in the Population Model as a management tool.

Dens that facilitate security and energy conservation during hibernation period are of significant value to black bears, and female bears exhibit a tendency to select tree cavity dens when available. Retention of large diameter live trees, large snags, and large fallen logs may be a valuable goal to benefit black bears in all forest management plans and programs.

CHAPTER 9

HOME RANGE, MOVEMENTS, AND HABITAT USE

Relative to most North American game species, black bears exhibit very large home ranges, and are known to travel great distances to reach abundant food sources (Amstrup and Beecham 1976, Lindzey and Meslow 1977, Garshelis and Pelton 1981, Warburton and Powell 1985, Smith and Pelton 1990, Wooding and Hardisky 1994). A thorough understanding of the movement patterns of bears may help agencies identify and manage distinct subpopulations within a state, and work with neighboring states to manage inter-state populations. Information about dispersal rates may aid in interpreting hunter-kill data, as it relates to emigration and immigration. Knowledge of the sources of bear-human conflict and effectiveness of translocation may aid in management of nuisance and depredation complaints.

We investigated black bear home range and movements on 2 New Mexico study areas during 1992-2000. Our objectives were to (1) document black bear home range size by sex and study area; (2) investigate seasonal movement patterns by sex and age category; (3) investigate general habitat use patterns on each study area; (4) examine dispersal of subadult males and females; (5) examine patterns of nuisance and depredation activities by sex and study area; and (6) compare movements of translocated bears by sex and age category.

METHODS

For analysis of home range and movements, we used aerial telemetry locations, capture and recapture locations, den locations, and locations of mortalities (including hunter kill or depredation kill locations). Locations were classified by season: den, precast (den emergence to 20 July), and mast (21 July to den entry). To eliminate autocorrelation of locations, we excluded recapture locations if the bear was captured more than once at the same trap site during the same trap period. When the interval between 2 locations was <5 days, we excluded the second location if the distance between the 2 locations was <1000 m for females or <1500 m for males.

Numerous studies of black bears have documented extensive movements to abundant food sources, especially during the fall foraging period. Although these distant locations are a significant part of a bear's lifetime home range, we wished to discriminate them from the locations representing areas of concentrated, multi-annual use. For each bear, we selected den locations and locations from the precast season. For each location, we determined the distance to its nearest neighbor. For each bear, we multiplied the maximum distance by 1.5, and this became our critical value. Any mast season location exceeding this critical distance from any den or precast location was considered a long-range movement. If the maximum distance was ascribed to an outlier

among the den and premast locations and the maximum distance was more than 2 times the second longest distance, we usually reclassified the outlier as a long-range movement, and reanalyzed based on the second longest nearest neighbor distance. In most of these circumstances, the outliers appeared to be associated with movements to summer foods (mostly during July) or return movements from distant den locations (mostly during February to April). For the few subadult bears determined to be dispersing as described below, we used the above criteria only for locations when the bears were resident in their natal range. During years of active dispersal, we did not classify any locations as long-range movements.

Home Range

Multi-annual total home ranges were estimated using all locations, while multi-annual primary home ranges were estimated excluding long-range movements. Home range was estimated using the 100% minimum convex polygon (MCP) method (Mohr 1947) and the 95% fixed kernel (FK) method with the least squares cross validation procedure as the smoothing parameter (Silverman 1986). Estimates were calculated using the Animal Movements extension (P. Hooze, USGS-BRD, Alaska Biological Science Center) developed for use with ArcView software (Environmental Systems Research Institute, Redlands, California). A minimum sample size of 30 locations was required for bears to be included in home range analyses. Mean home range size was compared by sex and study area using *t*-tests.

Movements

We estimated the center of each primary home range using the arithmetic mean. We then calculated an “activity radii” for each bear location as the distance between the location and the home range center (Dice and Clark 1953). To determine the effect of sample size on our ability to estimate the home range center, and thus activity radii, we calculated incremental mean activity radii for each bear by sample size, starting with the first 3 premast locations. We then calculated the percent change in the mean activity radius as sample size increased. Minimum sample size was achieved when the mean percent change fell below 5%. Bears with sample sizes below this number were excluded from analyses using activity radii. Differences in mean activity radius by sex, ageclass, season, and study area were tested using *t*-tests and analysis of variance (ANOVA), with individual bears as a random factor.

Habitat Use

We defined habitats using land cover data obtained from the New Mexico Gap Analysis Project (NMGAP, Thompson et al. 1996). These data included 42 land cover types, primarily based on dominant vegetation and canopy cover. For analysis of general use, we reclassified these land cover types into 6 broad

categories: closed forest/closed woodland, open forest, open woodland, open shrubland, open grassland/tundra, and other land cover.

We used bear location data compiled for home range analyses to document use of these habitat types by the bear populations on each study area. For these analyses, locations outside of New Mexico were excluded. For each bear location, a scan area was created with a radius corresponding to the median telemetry error for each study area (NSA = 200 m, SSA = 505 m). Scan areas were overlaid onto the NMGAP map and habitats found within the buffer area were determined. When more than 1 habitat type was found within a scan area, use was weighted by the inverse of the number of types within the scan area (ranging from 1-3). Percent use was defined by percent of locations within each habitat type by season.

We determined availability of habitat types using composite home range data. We created composites of the 100% MCP and the 95% FK total home ranges for all radio-transmitted bears, excluding the locations outside of New Mexico as described above. We also excluded the single long-range movement to Elephant Butte Lake (observed for a male on the SSA), because this single location would have greatly inflated the available habitat area. Relative distribution of habitat types within the composite home ranges was determined by assigning habitat type to random points generated at approximately 1 point/km². Patterns of selection versus avoidance of habitat types were estimated using use versus availability analyses (Neu et al. 1974).

Dispersal

We estimated dispersal rates using 2 samples of radio-transmitted juvenile bears. The first sample consisted of bears whose natal range was known (those handled as cubs or yearlings in the den). The second sample consisted of bears whose natal range was not verified (those captured as yearlings or subadults). Dispersal was determined by examining annual changes in pre-mast movements. We considered a bear dispersed when it moved from 1 pre-mast range to a second pre-mast range (with no overlap).

Nuisance or Depredation Activity and Post-translocation Movements

We identified areas of potential human conflict for bears on each study area. We restricted analyses to areas of predictable potential food sources, including towns, public campgrounds, and other known sources of garbage or food. Areas of unpredictable potential food sources, such as backcountry campsites, were not assessed. We determined percent of all MCP home ranges of bears >1 year old that overlapped these areas of potential human conflict. In addition, nuisance and depredation complaints reported to NMDGF were recorded for marked study bears. Percent of each study population involved in these complaints was determined by sex.

During the study period, several radio-collared study bears were translocated by NMDGF personnel due to nuisance or depredation activities. We documented post-translocation movements of radio-collared bears to determine rate of return.

RESULTS

Home Range

Mean total and primary home range size was larger for males than females ($P < 0.001$) on both study areas (Table 9-1). Total home range size varied greatly by individual, especially using the MCP method. Total MCP home range size ranged from 104.8 km² to 3,343.8 km² for males. Variation in FK home range size was not as great, but still notable. The largest home range size was that of a SSA adult male (M380) that made a single long-range movement to the vicinity of Elephant Butte Lake. Although this home range size greatly exceeded those of other males, it may actually reflect the potential areas used by SSA bears. Of 8 SSA males with estimated home ranges, 7 (88%) were not found for 1-4 periods exceeding 45 days, indicating many long-range movements were not documented. The single SSA male bear that was consistently located (M326) had a total MCP home range size of 847.1 km² and a FK home range size of 213.4 km². On the NSA, only 3 of 10 (30%) bears were missing for 1-3 periods exceeding 45 days. Therefore, home ranges were probably more accurately documented for NSA males than SSA males. No significant differences were found between NSA and SSA male total home ranges ($P \geq 0.39$), however the higher frequency of missing bears on the SSA may indicate total home ranges were larger.

Total MCP home range size ranged from 10.2 km² to 866.7 km² for females. Among females, the largest total home range size was that of a SSA adult female (F804) that appeared to have 2 distinct primary home ranges. One range was located within the study area, while the other was located within the Gila Wilderness. Most of the large sizes of other female total home ranges were attributable to isolated long-range movements. Mean total home range size was not significantly different by study area ($P \geq 0.25$). On the SSA, 15 of 26 (58%) female bears were not found for 1-2 periods exceeding 45 days, but only 4 of 35 (11%) females were missing for a single period exceeding 45 days on the NSA. This may indicate total home ranges were larger on the SSA.

Mean primary home range size estimates were approximately 3-5 times larger for males than females ($P \leq 0.01$) on both study areas (Table 9-1). Among males, ranges and means of primary home range size were very similar between study areas, and no differences were found ($P \geq 0.96$). Mean primary home range size estimates of SSA females were nearly twice as large as estimates for NSA females. The difference was significant for the MCP estimates ($t = -2.1$, df

= 27.0, $P = 0.05$) and slightly significant for the FK estimates ($t = -1.7$, $df = 24.6$, $P = 0.10$).

Table 9-1. Size (km²) of multi-annual minimum convex polygon and 95% fixed kernel home ranges for black bears monitored on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992-2000. All estimates differed by sex within study areas ($P < 0.001$) and estimates of primary home range differed between areas for females ($P \leq 0.003$).

Movements

Mean activity radius around home range centers was smaller during the premast season than during the mast season for all sex-age categories, except yearling females and SSA male yearlings ($P \leq 0.05$, Table 9-2). On both study areas, mean activity radii were larger for adult and subadult males than all other sex-age categories during the premast season and during the mast season ($P < 0.001$).

Among adult and subadult males, mean activity radius did not differ between study areas during either season ($P \geq 0.28$). Among all females and yearling males, mean activity radius was larger on the SSA than the NSA during the premast season ($t = -5.1$, $df = 775.2$, $P < 0.001$), but not during the mast season ($t = -0.3$, $df = 1899.0$, $P = 0.79$).

Mean activity radius was larger during years of oak failure than all other years for adult and subadult males on the NSA (16.2 vs. 9.1 km, $P < 0.001$) and the SSA (19.3 vs. 9.5 km, $P < 0.001$). The same was observed for all females and yearling males on the SSA (5.4 vs. 3.9 km, $P = 0.001$), however no difference was observed for that group on the NSA ($P = 0.21$).

On both study areas, mean activity radii of male bears displayed a gradual increase throughout the premast season, while mean activity radii of female bears remained relatively constant (Figure 9-1). On the NSA, both sexes appeared to increase movements during mid-August and continue to move until early October. On the SSA, both sexes increased movements during late August and continued to move widely through late October. Peaks of fall movements appeared to occur earlier for males on both study areas. Peaks also appeared to occur earlier on the NSA than the SSA.

Table 9-2. Activity radii (km) around home range centers for black bears monitored on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992-2000. Mean activity radius differed by season and sex for all age classes, except yearling males ($P = 0.05$).

Percent of all locations considered long movements (outside of primary home ranges) also increased during the fall mast season (Figure 9-2). On the NSA, from late August until early October, over 40% of male locations and over 30% of female locations were long-range movements. On the SSA, over 25% of female locations were long-range movements from late August to late October. For SSA males, sample sizes were smaller than other categories, therefore that group exhibited more variation, but in general more than 20% of male locations were long-range movements between mid August and late October.

Figure 9-1. Mean activity radius (km) around home range centers, by week, for male and female black bears monitored on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992-2000.

Figure 9-2. Percent of black bear locations considered long-range movements (outside of primary home ranges), by week, on the Northern Study Area (NSA) and the Southern Study Area (SSA), New Mexico, 1992-2000.

Habitat Use

Patterns of habitat use were very similar between the 2 study areas. On both study areas, analyses indicated bears were highly selective of the closed forest and woodland habitat types during all seasons, with >80% of locations occurring in these types (Table 9-3). Areas of open shrubland also were selected, but use and availability of this type was more limited. Areas of open woodland and open grassland were avoided, and most locations (96%, $n = 460$) within these habitats occurred within 500 m of the edge of closed-canopy habitats.

Table 9-3. Observed use versus availability of habitat types by black bears on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992-2000.

Area	Habitat type	Observed percent use by season			Percent in composite home range		Result $P < 0.001$

	<i>n</i>	2444	1176	1015			

^aNot significant relative to MCP composition

^bNot selected during premast season

Habitat use patterns differed slightly by sex during the premast season on both study areas, but closed forest and woodland habitats still accounted for >85% of use for both sexes. On the NSA, more male locations were found in open grassland habitats (4% vs. 2%) and agricultural lands (1% vs. 0%) than females ($X^2 = 13.1$, $df = 4$, $P = 0.01$, $n = 1883$). On the SSA, more male locations were found in open woodland habitats (3% vs. 1%) and open shrubland habitats (6% vs. 3%) than females ($X^2 = 24.0$, $df = 4$, $P < 0.001$, $n = 1170$).

Dispersal

No dispersal was observed among female bears whose natal range was known, however dispersal was observed among male bears (Table 9-4). Radio-telemetry monitoring ended prior to dispersal for most males (76%), due to shed transmitters, collar removal, mortality, or lost contact. Of males monitored until age 4, 100% dispersed from their natal range. Five dispersal movements were documented. Two males (40%) dispersed during fall of their yearling year, 2 males (40%) dispersed during fall of their second year, and 1 male dispersed during the spring of his third year (20%). Dispersal distance ranged from approximately 25-60 km. Interestingly, 2 littermates dispersed at the same time to the same area and made similar movements to fall mast.

In addition to these known dispersal observations, we also documented the probable dispersal of a male bear captured as a subadult. This bear appeared to disperse during late summer of its third year, when it moved approximately 45 km from its previous range and established a new home range. This individual was known to maintain this home range until fall of his fifth year.

Table 9-4. Rate of dispersal, by age, for juvenile black bears monitored with radio telemetry on the Northern and Southern Study Areas, New Mexico, 1993-2000.

Nuisance or Depredation Activity and Post-translocation Movements

On the NSA, radio-telemetry data was obtained for 52 females bears and 41 male bears >1 year old. Primary MCP home ranges of 81% of females and 90% of males overlapped areas of potential human conflict. The most common area of overlap was Philmont Scout Ranch, used by 65% of females and 90% of males. Public campgrounds were found within 10% of female and 34% of male home ranges. The towns of Eagle Nest, Ute Park, or Cimarron, or the Eagle Nest Reintegration Center were found within 15% of female and 39% of male home ranges.

On the SSA, radio-telemetry data were obtained for 41 females and 35 males >1 years old. Primary MCP home ranges of 3 (7%) females and 4 (11%) males overlapped areas of potential human conflict. Areas of overlap included 2 public campgrounds at Willow Creek and Snow Lake. None of the home ranges of SSA bears overlapped towns.

On the NSA, 14% of females and 20% of males >1 year old were known or suspected of potential nuisance or depredation activity ($n = 158$), but only 2% of females and 1% of males on the SSA were involved in these activities ($n = 154$, Table 9-5). Of 28 NSA bears involved in nuisance or depredation activities, half (50%) were attracted to towns with unsecured garbage or other available foods. Garbage was made available to bears most often by the use of open dumpsters lacking bear-resistant lids. Foods associated with homes included hummingbird feeders, pet foods, deer feed, and garbage. Nuisance activities of 7 bears (25%) were associated with Philmont camps and activities of 5 bears (18%) were associated with public campgrounds. Three depredation complaints (11%) arose from depredation of domestic pigs or apiaries.

Table 9-5. Percent of marked black bears >1 year old known or suspected of nuisance or depredation activities on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1992-1999.

Area	Sex	<i>n</i>	Percent suspected of nuisance activity	Percent causing nuisance or depredation complaints by management action			Total percent
				Hazed	Translocated	Killed	
NSA	Females	57	7	2	4	2	14
	Males	101	4	3	8	5	20
SSA	Females	56	0	0	2 ^a	0	2
	Males	98	1	0	0	0	1

^a Both bears were translocated into the study area from outside its boundary

On the SSA, both female bears translocated because of nuisance activity were actually moved onto the study area from outside its boundary. One incident arose at a public campground and the other was associated with a backcountry camp. The single male bear suspected of depredation activity was found shot dead near a cattle carcass. It was unknown if the bear was responsible for the death of the cow.

Post-translocation movements were documented following 11 translocations of 8 bears (Table 9-6). Translocation distances ranged from 26-84 km and overall rate of return was 73%. Return movements took from approximately 1-328 days. Return rate of adult bears was 100%, and each individual appeared to begin return movements immediately following

translocation. Return rate of subadult bears was 57%, and 3 of 4 bears that did not attempt return movements were males.

DISCUSSION

Evidence indicated bears on the SSA, in general, moved over larger areas than bears on the NSA. Mean premast activity radii and primary home range size was larger for females on the SSA. Although no differences in male home range size or activity radii were found between study areas, the higher frequency of missing bears on the SSA suggested they may have moved greater distances than documented. Many have postulated home range size is an indication of habitat quality. The premise is when food is abundant and evenly distributed animals do not need to search far for food. When food is scarce and distribution is patchy, animals need to move more widely in search of food. We do not have detailed information on the distribution of food plants on each study area, but examination of habitat data showed that availability of mast-producing habitats did not differ between study areas. However, relative consumption of premast foods did appear to differ between study areas (see Chapter 5). On the NSA, the premast diet was dominated by grasses. On the SSA, the premast diet was characterized by less consumption of grasses, and greater consumption of mast and woody plants. The more arid conditions of the SSA, coupled with livestock grazing, may limit the availability of grasses to bears, and compel individuals to search more widely for other foods, such as juniper berries.

Table 9-6. Rate of return, by sex-age category, for nuisance bears translocated into or away from the Northern and Southern Study Areas, New Mexico, 1993-2000.

Sex	Age class	<i>n</i>	Percent Returned	Distance Moved	Details
Female	Adult	2	100%	38-47 km	Both bears previously moved as subadults, both returned
	Subadult	4	75%	25-58 km	The bear that did not return moved to another human development
Male	Adult	2	100%	45 km	One individual moved twice
	Subadult	3	0%	65-85 km	All bears appeared to establish home ranges in new area, no further nuisance activity documented

The fall foraging period lasted for over 2 months. On the NSA, bears ranged widely beginning in early August and ending during early to mid October. On the SSA, fall movements were less well-defined, but ranged from mid August

to late October. On both study areas, peaks of male movements appeared to occur earlier than those of females, and initiation of long-range movements was earlier for males on the NSA. Earlier initiation of fall movements to oak stands by male black bears also was observed in Great Smoky Mountain National Park (Garshelis and Pelton 1981).

Increased fall travel distances during years of food shortage have been reported in other bear studies (Garshelis and Pelton 1981, Beck 1991). Most season activity radii of black bears in New Mexico were significantly larger during years of oak failure for most sex-age categories, indicating bears may have had to travel farther in search of food when oak production failed. The increased movements and unfamiliarity of distant areas may make bears more vulnerable to hunting. Higher bear harvest levels have been associated with shortages of natural foods in Massachusetts (McDonald et al. 1994) and Minnesota (Noyce and Garshelis 1997). This has important ramifications for interpreting and predicting fall harvest of bears.

Analyses of habitat use indicated bear movements were strongly associated with closed forest and closed woodland habitat types. Open habitats, including grasslands and open woodlands, appeared to be avoided, particularly by female bears. Use of the open shrubland habitat was relatively low, but was higher than expected given its low occurrence. Oak species are an important component of many montane shrubland communities in New Mexico, and general observations throughout the study period indicated bears sought these habitats during the fall foraging period. Based on ground knowledge of the study areas, we believe shrubland communities were under-represented in the NMGAP landcover map (Thompson et al. 1996) we used for habitat analysis (see Chapter 11). This probably limited our ability to assess actual use of shrubland habitat. Selection for closed canopy habitats, avoidance of open habitats, and use of edges by black bears have been reported in other black bear studies in the West (Lindzey and Meslow 1977, LeCount and Yarchin 1990).

Overlap of bear home ranges with areas of potential human conflict was very different between the 2 study areas. Most bears on the NSA had 1 or several sources of human-related food within their primary home ranges, but few bears on the SSA had access to predictable human-related foods. Given these circumstances, it is easy to explain the substantial depredation mortality observed on the NSA and the lack of such mortality on the SSA (see Chapter 7).

Despite the potential for conflict on the NSA, most bears did not engage in nuisance or depredation activities. At least 35 female study bears had home ranges partly or entirely within Philmont Scout Ranch, however only 3 of these bears created nuisance problems requiring management action. Likewise, at least 37 male study bears used areas of Philmont, but only 2 were involved in nuisance complaints. Throughout the study period, Philmont maintained strict

guidelines for storing foods in established camps and on the trail. These precautions appeared to be effective at minimizing bear-human conflict.

Compared to bears using areas of Philmont, far fewer study bears (9 females and 17 males) had home ranges encompassing towns or campgrounds. However, the majority of documented conflict was associated with these areas. In each of the 3 towns close to the NSA and the Eagle Nest Reintegration Center, garbage disposal was achieved using non bear-resistant dumpsters, often distributed throughout residential areas. These dumpsters were probably the initial attractant drawing bears into human-populated areas. The reward of high-calorie food obtained from dumpsters was probably enough to overcome the natural wariness of bears to humans (Herrero 1989). Human habituation, or loss of innate fear of humans, has been directly associated with use of human-related foods by black and grizzly bears (Hastings et al. 1989, Herrero 1989). In human-populated areas of the NSA, the transition from wariness to human habituation probably fit the circumstances described by Herrero (1989), whereby over time, when use of human-related foods did not result in harm or harassment to the bear, habituation developed. Increased use of other human-related foods, such as hummingbird feeders or pet food, was a predictable outcome of this progression. In the end, bears and humans can be negatively impacted by these events. Mortality of male and female bears was observed on the NSA due to nuisance and depredation problems. In most cases, bears were destroyed because they were considered a threat to human safety. In addition, many incidents of human injury and fatality from black and grizzly bears have been attributed to human habituation (Herrero 1989).

Increases in black bear nuisance problems have been correlated with shortages in natural foods (Rogers 1976, Rogers 1987). The small number of depredation complaints recorded on an annual basis, and the occurrence of only 1 oak failure on the NSA prevented us from drawing any conclusions about the effect of natural food availability on bear problems in New Mexico. However, general observation in the region of the NSA hinted at an association of bear problems with spring and summer periods lacking rainfall. Analyses of bear complaints relative to fall mast production and spring to summer conditions is needed in New Mexico.

Use of translocation as a means of solving nuisance or depredation complaints had variable success. All translocated adult bears returned to their original home range within days or months of their translocation. However, in most cases the time elapsed before their return did allow for immediate resolution of the problem. Some translocations of subadult bears, especially males, were successful in that bears remained in the new area, and did not resume nuisance behavior. This was probably due to behavioral differences between sex-age categories. Subadult male bears may not have attempted return to their previous home range, because of the dispersing behavior characteristic of this age class. On the contrary, adult bears, and even subadult

females displayed a high degree of home range fidelity during our study, indicating they would most likely show homing behavior following translocation. Homing behavior of translocated bears has been widely reported and an inverse relationship between distance moved and probability of return was evident in all studies (Sauer et al. 1969, Beeman and Pelton 1976, McArthur 1981, Rogers 1986). In general, bears translocated more than 65 km from the capture site were less likely to exhibit homing behavior. Despite some success, translocation is not without cost to bears. Survival rates of translocated bears were found to be only 23% in Virginia and the primary cause of death was automobile collisions (Comly-Gericke and Vaughan 1997).

MANAGEMENT IMPLICATIONS

Analyses of bear movement data and distribution among habitat types on the 2 study areas illustrated the importance of distinguishing how male and female bears use the landscape differently. These analyses also indicate the importance of considering the season and condition of food supply when drawing conclusions about the presence of bears in specific locations.

Three of the largest tracts of bear habitat in New Mexico (the San Juan complex, the Sangre de Cristo complex, and the Gila complex) are contiguous with bear habitat in Colorado or Arizona (see Chapter 11). Two small tracts (the Bootheel region and the Guadalupe region) share habitat with Arizona or Texas. Evidence indicates bears commonly cross state boundaries during fall foraging and dispersal. Therefore, bear management in New Mexico is not independent of these other states. Some understanding of the population trend in these other states is vital for estimating the potential impact of immigration and emigration on New Mexico black bear populations.

Analysis indicated a small percentage of individuals within a bear population engage in nuisance and depredation activities. Most documented bear problems were associated with human-related foods, especially garbage. Efforts to reduce accessibility of human-related foods will be instrumental in reducing the likelihood of bear problems on an annual basis. More information is needed on the relationships of natural food availability and bear problems. Increase in nuisance problems have been associated with food shortage in other regions. Therefore, during years of low natural food abundance, problems can be expected to increase above the average level in New Mexico.

There is an apparent differential between subadult and adult bears regarding homing after translocation. This difference suggests that choices about relocating nuisance or depredating bears need to consider age and sex of the animal in addition to other factors surrounding the complaint.

CHAPTER 10

POPULATION DENSITY AND SEX-AGE COMPOSITION

For wildlife managers, 2 of the most desirable facts about a wildlife population are a firm estimate of total number of individuals and a tally by sex and age category. Sound wildlife management can be, and most often is practiced in the absence of these data. Nonetheless, population data are invaluable for monitoring population trend, setting hunt regulations, and providing adequate suitable habitat. Estimates of density and sex-age composition are among the most difficult values to obtain for wild populations, and black bears present some special challenges. Their solitary nature, forest-dwelling habit, and low densities make them difficult to enumerate using survey methods common for other big game species. Most often mark-recapture methods have been used to estimate black bear density (LeCount 1982, Beecham 1983, Miller et al. 1987, Garshelis 1992, Clark and Smith 1994).

At the beginning of this study, reliable information on population size and structure was lacking in New Mexico. The NMDGF had a long-standing populations estimate of 3000 bears statewide; however the means by which this estimate was deduced were not available. Our objective was to determine density and sex-age composition of study populations annually and with all years combined. This information would be valuable in estimating statewide and regional population numbers and for comparison of the sex-age composition of the live population to that of hunter-killed bears.

METHODS

Although the number of captures and recaptures were numerous, our trapping effort was primarily designed to capture an increasing sample of unmarked adult females. For this reason, it did not lend itself to a traditional capture-recapture analysis. We used population reconstruction (Eberhardt and Knight 1996), or backdating, to estimate a minimum population size of bears on each study area. This technique simply counts each individual as part of a study population during years when it was known or presumed to be resident, based on knowledge of its age. To translate this count into a density estimate, the critical element becomes the size of the area occupied by the individuals.

We defined a multi-year "effective sampling area" based on distribution of trap sites (Caughley 1977, Clark and Smith 1994). For each sex, we applied a buffer around each trap site equal to the mean activity radius of adult bears. We used the mean activity radius for the time period before most bears began to make long-range movements to fall mast (1 May – 12 August, see Chapter 9). We also restricted trap sites to those trapped within this period. The buffer areas around each trap were merged into a composite, and this became our effective sampling area. On the NSA, sampling areas used were 297.1 km² for females

and 545.4 km² for males. On the SSA, areas used were 538.6 km² for females and 969.2 km² for males. In essence, size of the area differed by sex, based on observed differences in movement patterns. Because males ranged over larger areas than females, we were able to sample a larger area for males than females using a single trap site.

We constructed a table of bears known alive during each year, by backdating from the last known observation of each study bear. Because no dispersal was observed among females (see Chapter 9), we counted bears as resident during all years if they were captured during the 1 May-12 August season. If they were captured during the mast season, they were counted only if they were known from radio-telemetry monitoring to reside within the effective sampling area. Female offspring of resident females were counted as residents. Due to observed dispersal patterns of males (see Chapter 9), we used different criteria. For males captured as adults, we could not assume they were born on the effective sampling area, therefore we counted them as resident only back to the age of 4 years. For males captured only as subadults and not monitored with radio-telemetry, we counted them as resident only during years when they were captured. For males captured as yearlings, we backdated until birth. Male offspring of resident females were counted as resident only as yearlings or until dispersal was observed through radio-telemetry monitoring.

We determined annual and mean population densities of bears ≥ 1 year old based on these counts. We did not assume we captured all resident bears within the sampling area; therefore these estimates were considered minimum. Because more female bears were monitored with radio-telemetry than male bears, more information on residency and survival was obtained for female bears. Therefore, although we used this method to estimate the sex-age composition of the populations, we recognized it could be biased toward females. Relative proportions of yearlings were also probably underestimated. Because capture probabilities appeared to be lower for this age class, and most bears were captured as adults, bears that did not survive their yearling year would not appear in our analyses.

RESULTS

Estimates of adult and subadult densities remained relatively constant from year to year, on both study areas (Table 10-1). Number of females, particularly adult females, varied little between years. Number of males generally decreased over the years of study; however this decrease may have been due to a reduction in trapping effort rather than an actual change in numbers. Densities of yearlings were more variable. Bear density appeared to be higher on the NSA than the SSA. Mean estimates of adult bears were 45% lower for females on the SSA and 29% lower for males.

Relative proportions of sex-age categories varied annually, with most of the changes observed in the yearling age class. Proportions of subadult males also varied, with peaks observed during 1993-95 on the NSA and 1994-95 on the SSA.

Table 10-1. Density (bears/100 km²) of adult (≥5 years old), subadult (2-4 years old), and yearling (1 year old) black bears sampled on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993-1999^a.

^aEstimates were derived using population reconstruction within an effective sampling area based on distribution of traps.

Population sex-age composition was very similar for the 2 study areas (Table 10-2). Adult females constituted approximately 35% and adult males accounted for 18-23% of study populations. Relative proportions of yearlings varied annually.

DISCUSSION

Although this method had limitations, we believe the estimates derived were relatively accurate, particularly for adult and subadult bears. The raw numbers of individuals counted within the sampling areas were similar for the 2 study areas, as expected considering the nearly equal trapping success (see Chapter 4). The primary factors contributing to differences in density estimates

were observed difference between study areas in activity radius and the differences between study areas in total area sampled. The smaller activity radii observed on the NSA, coupled with the more restricted study area boundary, resulted in smaller effective sampling areas, thus higher densities. The activity radius values used to generate the effective sampling error appeared to be fairly accurate, based on comparisons with the composite primary MCP home ranges (see Chapter 9) for the individuals counted as residents (Figures 10-1 and 10-2). For females, the composite home range areas were only 5-6% larger than the effective sampling area, and most individual home ranges were well within its boundary. For males, the composite home range area was 28-59% larger, but most individual home ranges were still contained within the sampling area. A high degree of home range overlap was observed between individuals, especially males. Therefore, the composite home range areas would likely contain more unsampled individuals, especially on the outer edges, well away from trap sites.

Table 10-2. Estimated proportions of adults (≥ 5 years old), subadults (2-4 years old), and yearlings (1 year old) within black bear populations sampled on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico, 1993-1999^a.

Area	Sex	Age class	Year							All Years
			1993	1994	1995	1996	1997	1998	1999

^aEstimates were derived using population reconstruction within an effective sampling area based on distribution of traps.

Although density estimates were quite different by study area, estimates of sex-age composition were remarkably similar. Given similar survival rates observed on the 2 study areas (see Chapter 7), our estimates of density and composition appear relatively accurate. However, densities observed on the NSA may have been higher than in similar habitat where hunting was not restricted. Our data are not sufficient to rigorously assess that question.

Figure 10-1. Size of the effective sampling area used for estimating black bear density, relative to primary minimum convex polygon home ranges of resident bears on the Northern Study Area, New Mexico, 1992-2000.

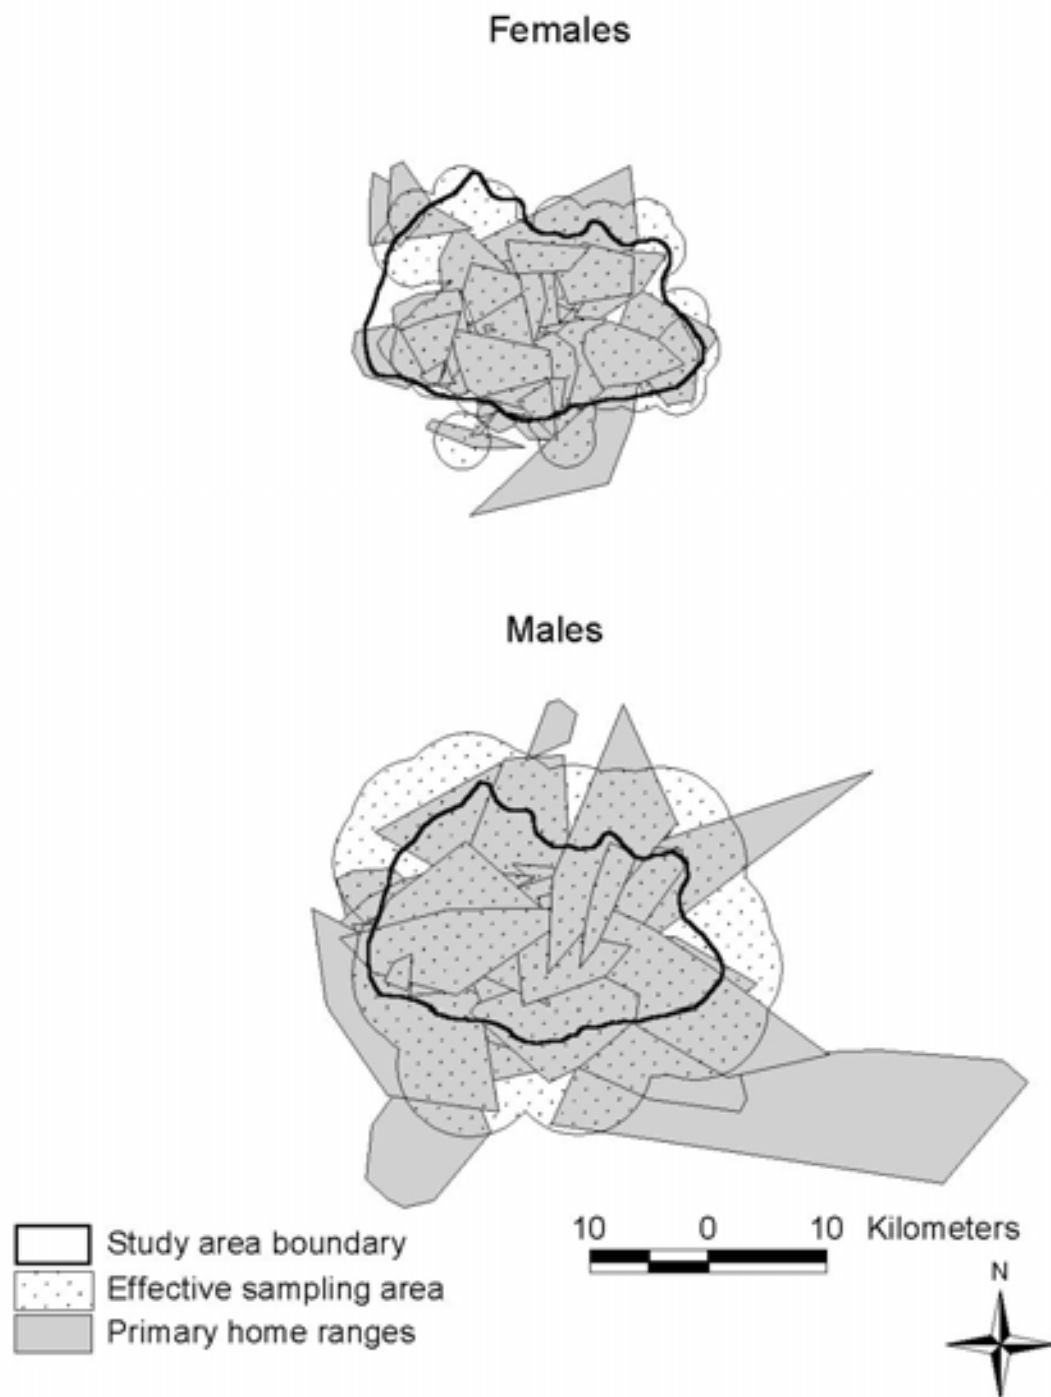

Figure 10-2. Size of the effective sampling area used for estimating black bear density, relative to primary minimum convex polygon home ranges of resident bears on the Southern Study Area, New Mexico, 1992-2000.

Densities and proportions of yearlings were quite variable among years. For each study area, the years of lowest yearling density (1995 on the NSA, 1996 on the SSA) corresponded to years following oak failure (see Chapter 6). On both study areas, the densities and proportions of yearlings were lower for males than for females. We suspect this was a product of the sampling and estimation method, and did not accurately reflect true values. In any given year, most yearlings counted within the sampling area were offspring of resident females, not trapped bears. Because the male sampling area was larger than the female's, there were likely unsampled females within it. Because we could not count their offspring, the resulting density estimates for male yearlings were lower than those of females. The density estimates for females in these age classes were probably more accurate.

Black bear density has been estimated in many regions of North America, primarily using mark-recapture or mark-resight methods. The variability of these estimates is tremendous, with densities as low as 1.8 bears/100 km² in the Snowy Mountains of southeast Wyoming (Grogan and Lindzey 1999) to 149 bears/km² on a coastal island in Washington (Lindzey and Meslow 1977). Within the Southwest, density estimates have ranged from 12-16 bears/100 km² in west-central Colorado (Beck 1991) to 71 bears/100 km² in north-central Arizona (LeCount 1987). Our density estimates appeared reasonable in the context of these other studies.

MANAGEMENT IMPLICATIONS

The density estimates obtained for the study areas can be used in conjunction with habitat data (see Chapter 11) to estimate statewide and regional population sizes. However, these estimates must be used with caution. Arguably, our study was conducted within some of the most productive bear habitat in New Mexico, particularly the NSA. Direct extrapolation of these density values to all areas of bear habitat would not be realistic.

The sex-age composition estimated for the study areas also can be compared to the structure of hunter kill data and simulated population structures generated using the bear population model (see Chapter 14). These analyses may aid in current and future interpretation of bear population trend, as reflected in the harvest data.

CHAPTER 11

A MODEL OF STATEWIDE HABITAT SUITABILITY AND POPULATION SIZE

Understanding the population status and trend of large carnivores, such as bears, over large landscapes is constrained by limited availability of detailed empirical data and few approaches to analysis and display of spatial information (Merrill et al. 1999). Habitat analysis using GIS technologies has proven useful for management of wildlife in general (Scott et al. 1993, Horino and Miura 2000) and black bears in particular (Clark et al. 1993, van Manen and Pelton 1997). These approaches can be useful to forecast future impacts of human population growth or habitat alteration. Van Manen et al. (1997) considered forecasting capabilities fundamental to the management process.

In this chapter, we describe the New Mexico landscape from the perspective of bear habitat suitability. Specifically, we make spatial predictions as to potential availability of mast species and the potential for human interaction. Our objectives were to: (1) predict suitable black bear habitat in New Mexico, (2) derive associated statewide and regional population estimates, and (3) analyze potential human influences on bear habitat. These objectives involved GIS analyses of bear habitat associations based on habitat use and movements observed on the 2 study areas. These associations were applied to a land cover map of New Mexico and other spatial criteria to depict predicted suitable bear habitat. Factors (roads, human population density, hunter kills) known to affect bear populations were overlaid with suitable habitat to develop spatially explicit perspectives on potential hunting mortality and bear-human conflict.

Information gathered from these exercises should help managers better understand the status of black bears across the state and serve as the basis for black bear management. The bear habitat model is a tool that identifies where bears have the potential to occur, the spatial boundaries of distinct populations, the degree of isolation between populations, and whether landscape characteristics differ among populations. These perspectives can aid in forecasting bear management needs and challenges.

METHODS

Habitat Model Development

A spatial model predicting the extent of suitable black bear habitat was developed using a rule-based system with GIS technologies, based on the New Mexico Gap Analysis (NMGAP) land cover map (Thompson et al. 1996) and biological information derived from field studies during 1992-2000. The habitat model was developed using ESRI Arc/View script language. The NMGAP land cover map includes 42 cover classes, described by dominant vegetation and canopy cover. Each of these cover classes was assigned to 1 of 4 categories of

relative suitability for bears based on habitat use observed on the 2 study areas (see Chapter 9) and cover type descriptions. Suitability was rated as primary, secondary, edge use, and no use (Table 11-1). Cover classes rated as primary included all closed-canopy forest and woodland types, because more than 80% of bear locations were found within these types. Cover classes rated as secondary included shrubland types used more than expected, but accounting for <10% of total use. Cover classes rated as edge use included open woodland and grassland types used less than expected. Analyses indicated these types were used by bears, but usually in close proximity to more suitable habitats. Cover classes associated with humans, such as agriculture or urban, were rated as no use. Desert cover types also were classified as no use.

Each land cover class also was assigned to 1 of 3 categories of relative mast production potential, based on cover type descriptions (Thompson et al. 1996) and occurrence of oak, juniper, or pinyon species within cover classes. Categories were high, poor, and no mast production potential.

The habitat model first selected all land cover classes classified as primary. Secondary types were then selected only if they were adjacent to a primary type. Edge use types were then selected if they were adjacent to a primary type, and only that portion within a 500 m buffer from the primary type was included in predicted habitat.

When these areas were identified, we used GIS analyses in the model determine the area of each contiguous tract of suitable habitat (regardless of its habitat suitability score). Tracts >300 km² were selected as suitable habitat. This size represented the approximate area supporting 50 individual bears based on density data from the NSA (see Chapter 10), and we deemed this a “minimum sustainable population”. Also, tracts >20 km² (large enough to support 1-2 bears based on home range data) were selected only if they were within 15 km of a habitat tract large enough for a minimum sustainable population.. All other tracts were considered too small or too isolated to be included in the final model.

The model was designed to allow users to vary the habitat scores for each land cover class, minimum tract size for a sustainable population, minimum tract size for a single individual, and maximum distance that an individual must be from viable population before it is considered too isolated from the population. Predictions of bear habitat reported here were based on values described above.

The model was designed to generate 2 maps of black bear habitat. The first was the detailed map described above. The second was a generalized distribution map that identified major regions of bear habitat. To develop this map, internal, unselected polygons were absorbed and the boundaries were simplified by expansion and shrinking of the boundary. This eliminated much of the reticulation and complexity of the polygon boundary. We found that doing this process twice resulted in a better generalization.

Table 11-1. Habitat suitability and mast potential assignments used in the statewide black bear habitat model for New Mexico; land cover classes are from Thompson et al. (1996).

NMGAP Code	Description	Suitability	Mast potential

Estimates of statewide and regional black bear population size were derived by extrapolating mean density estimates from the 2 study areas (see Chapter 9) to areas of primary habitat. Density estimates from the NSA were used to estimate population size on the San Juan and Sangre de Cristo complexes. Density estimates from the SSA were used for all other regions.

GIS data and related metadata (Appendix B) and the habitat model (Appendix C) are included on a CD associated with this report. The habitat model is written in ESRI Arc/View script language and this package, with Spatial Analyst is needed for its use. The script language used for the New Mexico bear habitat model is contained in a file on the CDs associated with this report.

Hunter-Kill Locations

We used locations (UTM coordinates reported to the nearest 1000 m) recorded for hunter-killed bears obtained from the NMDGF harvest data (see Chapter 13) to compile a point file of bear kill locations. Accuracy of data was verified by comparing the recorded GMU with the recorded location, and obvious mistakes were corrected. Records for which the numeric portion of the GMU did not match with valid coordinates were discarded from analyses.

A total of 3,047 records of hunter-killed bears were available for the years 1990-1999, but 420 records (14%) were discarded due to a lack of UTM coordinates or UTM coordinates inconsistent with the GMU recorded. Examination of relative numbers of discarded records by year and GMU did not indicate any bias in the remaining sample of 2,627 records.

Human Interface

We created a coverage depicting total road length within the mean activity radius for female and male bears during the fall season (1 September-den entry, see Chapter 9). Mean activity radii were calculated for bears on both study areas, and a radius of 7.0 km was used for females and 12.0 km was used for males. A coverage depicting New Mexico roads was obtained from the U.S. Census Bureau (<http://www.uscensus.gov>). Road length was tabulated for each region. Analysis of total length of secondary roads within female (7 km) and male (12 km) fall activity radii was designed to estimate the potential length of road a bear might encounter during months of fall hunting. These data were derived by calculating the length of roads within 7-km or 12-km radii of points distributed at 1-km intervals across all of New Mexico.

A coverage of U.S. census blocks was used to evaluate distribution of bear habitat relative to human populations. Population blocks with human residential density >1 person/ha and >5 households were identified. Buffers created around these population centers represented areas within 5-20 20 km.

Conceptually, we viewed human activity relative to potential effect on the bear population. Bear hunters pose the greatest relative direct effect on a bear population, therefore we tried to obtain available information on distribution and magnitude of bear hunting activity statewide. Secondly, human activity on the landscape can cause significant indirect and direct influence on bear distribution and mortality (e.g., interaction with or avoidance of recreationists, bear mortality to depredation complaints or vehicle collision). In addition to bear mortality, interactions with humans can be highly visible events. We sought spatial data that would identify the degree of human use (not including recreationists) on the landscape. Recreationists were considered a separate group. Their interactions with bears are varied but generally present seasonal and dispersed effects. Residential and recreational uses were conceptually separated not only because of their effect on the bear population but to the social aspects of management. A nuisance bear is different to a resident versus a recreationist regarding the type of mitigation possible.

With this conceptual framework we searched for data to develop indices of human use of the landscape. We directed our search toward data that were statewide in scope. NMDGF harvest survey data were obtained, compiled, and linked to GMU coverages to depict relative hunter occurrence on the landscape. Similarly, angler survey data obtained from NMDGF were linked to a coverage of New Mexico fishing waters. We anticipated that these data will represent areas of possible hunter/angler-bear interaction. We also made attempted to obtain United States Forest Service (USFS) Lands spatial data as they contain a significant portion of bear habitat in New Mexico. We looked for spatially explicit measures of use and locations of facilities. We acquired recreation data from the USFS including limited recreation user days data and point locations of recreation facilities. In addition, we acquired recreation user days data from the New Mexico State Parks and the National Park Service.

RESULTS

Predicted Suitable Habitat

The habitat model prediction depicted prospective distribution of suitable black bear habitat (Figure 11-1) across approximately 58,939 km² (5.9 million hectares or 14.6 million acres). Simplification of the boundaries identified 10 distinct regions of predicted black bear habitat: 4 large regions including the San Juan complex, the Sangre de Cristo complex, the Gila complex, and the Sacramento region; 3 smaller, relatively isolated tracts including the Zuni region, Mt. Taylor region, and Sandia/Manzano region; and 3 small regions connected to larger range outside New Mexico, including the Chuska region, Bootheel region, and the Guadalupe region. The simplification process did not distinguish the San Juan complex and the Sangre de Cristo complex. We artificially separated these complexes, with the boundary defined as the Rio Grande. All applicable summaries reported here use this stratification of the state.

Predicted Suitable Habitat for Black Bears in New Mexico

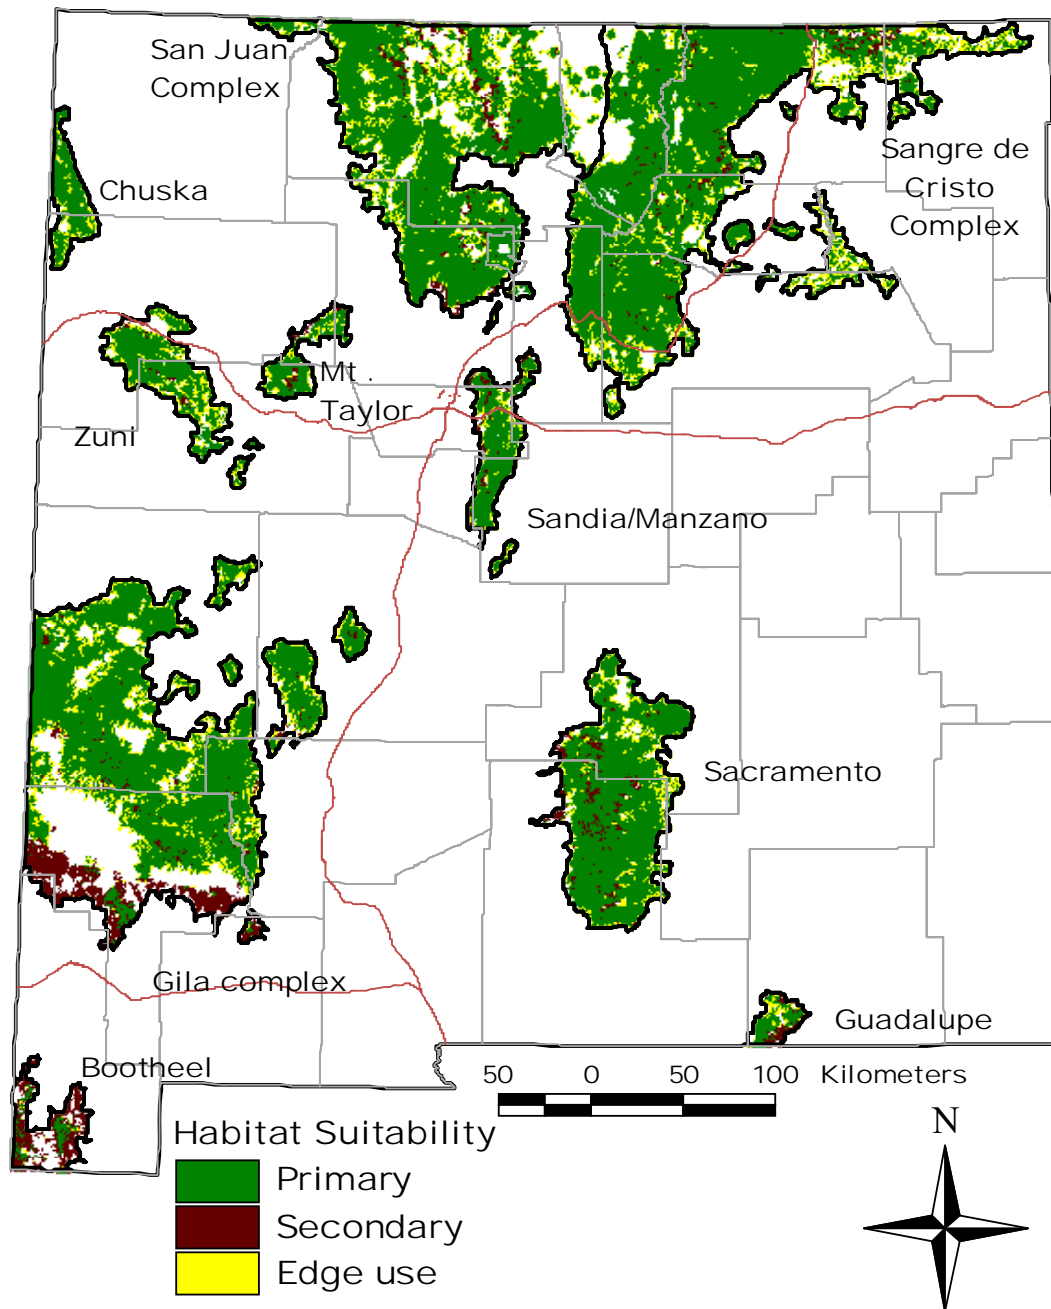

Figure 11-1. Map of predicted suitable habitat for black bear in New Mexico.

Of the 5.9 million ha of suitable habitat, 75% was comprised of primary cover types, 7% was comprised of secondary cover types, and 18% was comprised of edge use cover types (Table 11-2). Relative proportions of these types varied among regions. Most notably, the Bootheel region was comprised of relatively little primary habitat. Among the 4 large regions, the Gila complex had less primary habitat and more secondary habitat (Table 11-2).

Mast potential within suitable bear habitat showed some variability among regions (Figure 11-2). Areas of poor mast production potential were associated with higher elevations, especially in the San Juan complex, the Sangre de Cristo complex, the Gila complex, and the Sacramento region. When primary habitat was overlaid with mast production potential, only 280 km² was found to be >7.0 km from areas of high mast production potential. This distance corresponds to the observed mast season activity radius of female bears. That limited area with no mast production potential was located within the highest elevations of the Pecos Wilderness in the Sangre de Cristo complex.

Land ownership differed among the regions (Table 11-2). Nearly half of the predicted suitable bear habitat was managed by the USFS (Figure 11-3). Private landowners were the second most predominant stewards bear habitat, with about one third of all lands under private ownership. Tribal lands comprised about 10% of bear habitat, but it was concentrated in 3 regions. All of the Chuska range was situated within the Navajo Reservation, and large portions of the San Juan complex and the Sacramento region were found within the Jicarilla Apache and Mescalero Reservations, respectively. State lands and Bureau of Land Management properties constitute a relatively small portion of New Mexico bear habitat (Figure 11-3).

Human Interface

Locations of hunter-killed bears overlaid with the predicted habitat indicated strong corroboration of the habitat model predictions of habitat distribution (Figure 11-4). Significant tracts with no recorded bear kills were tribal lands and the Guadalupe and Bootheel regions. The Sandia range found within the north part of the Sandia/Manzano region also lacked records of bear kills. Overall, 95% ($n = 2,488$) of the bear kills occurred within the regional boundaries of predicted bear habitat. Of the 5% occurring outside boundaries, most were located north of the Gila complex. Bear kills are expected outside of predicted habitat because of occurrence of transient bears and slight errors in the predictive model.

Total road length within a female activity radius was highly variable statewide (Figure 11-5), but relatively uniform for a male activity radius (Figure 11-6). Approximately 40% of the bear habitat had >120 km of road within a

female activity radius, while greater than 80% of the habitat had >120 km of road within a male activity radius.

Location of Bear Kills by Hunters 1990-1999

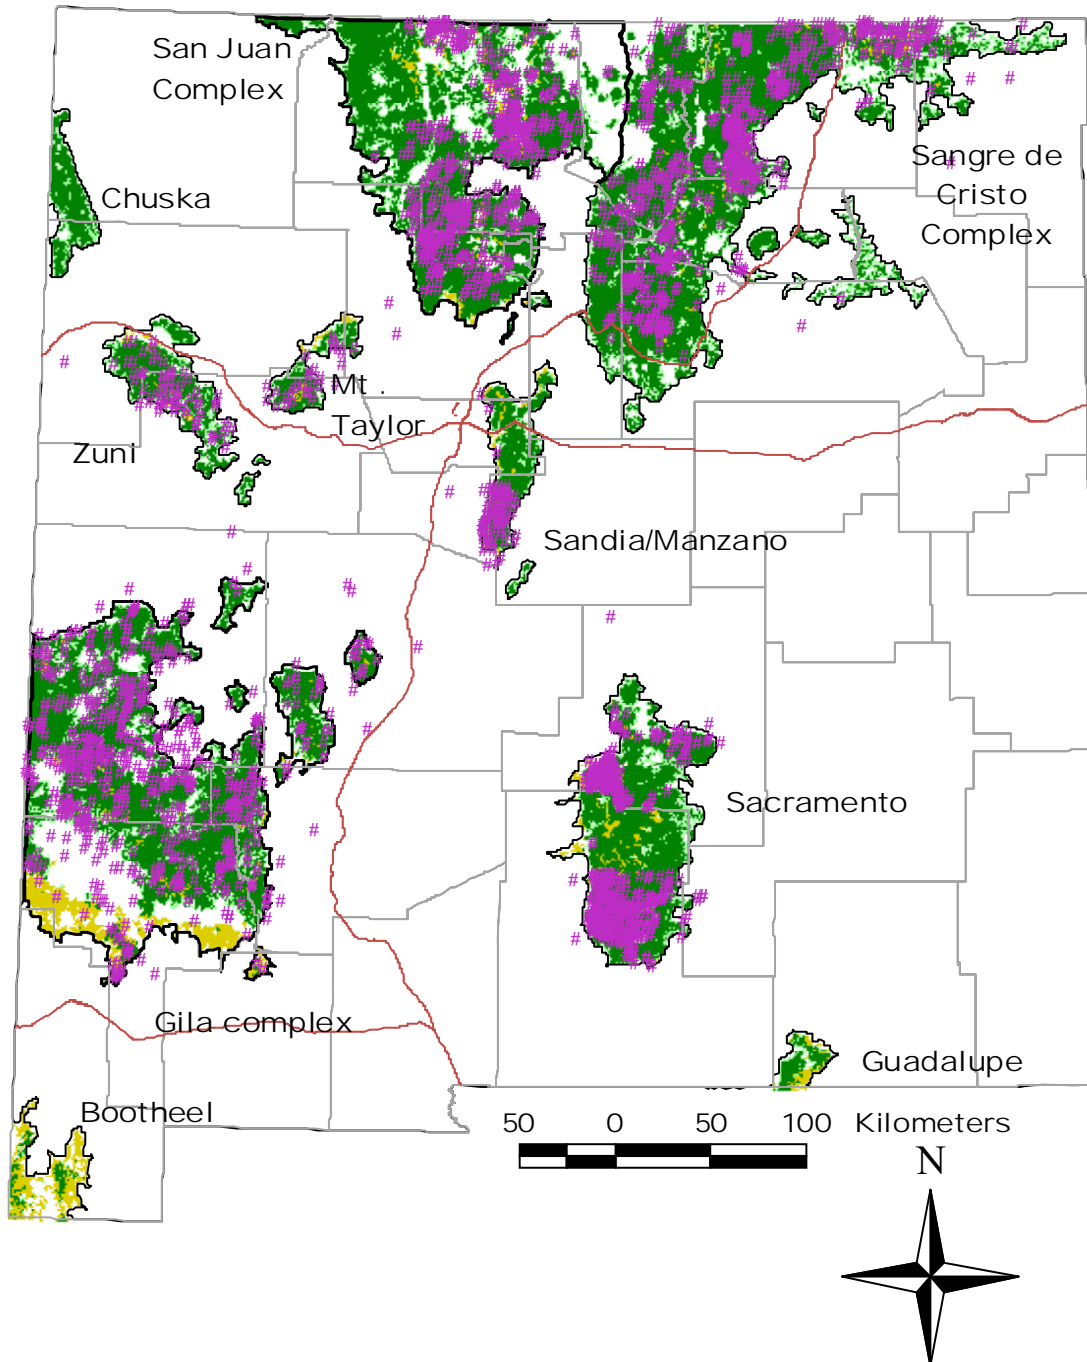

Figure 11-4. Distribution of reported bear kills by hunters from 1990 to 1999.

Relative Extent of Roads within Female Black Bear Fall Activity Radius

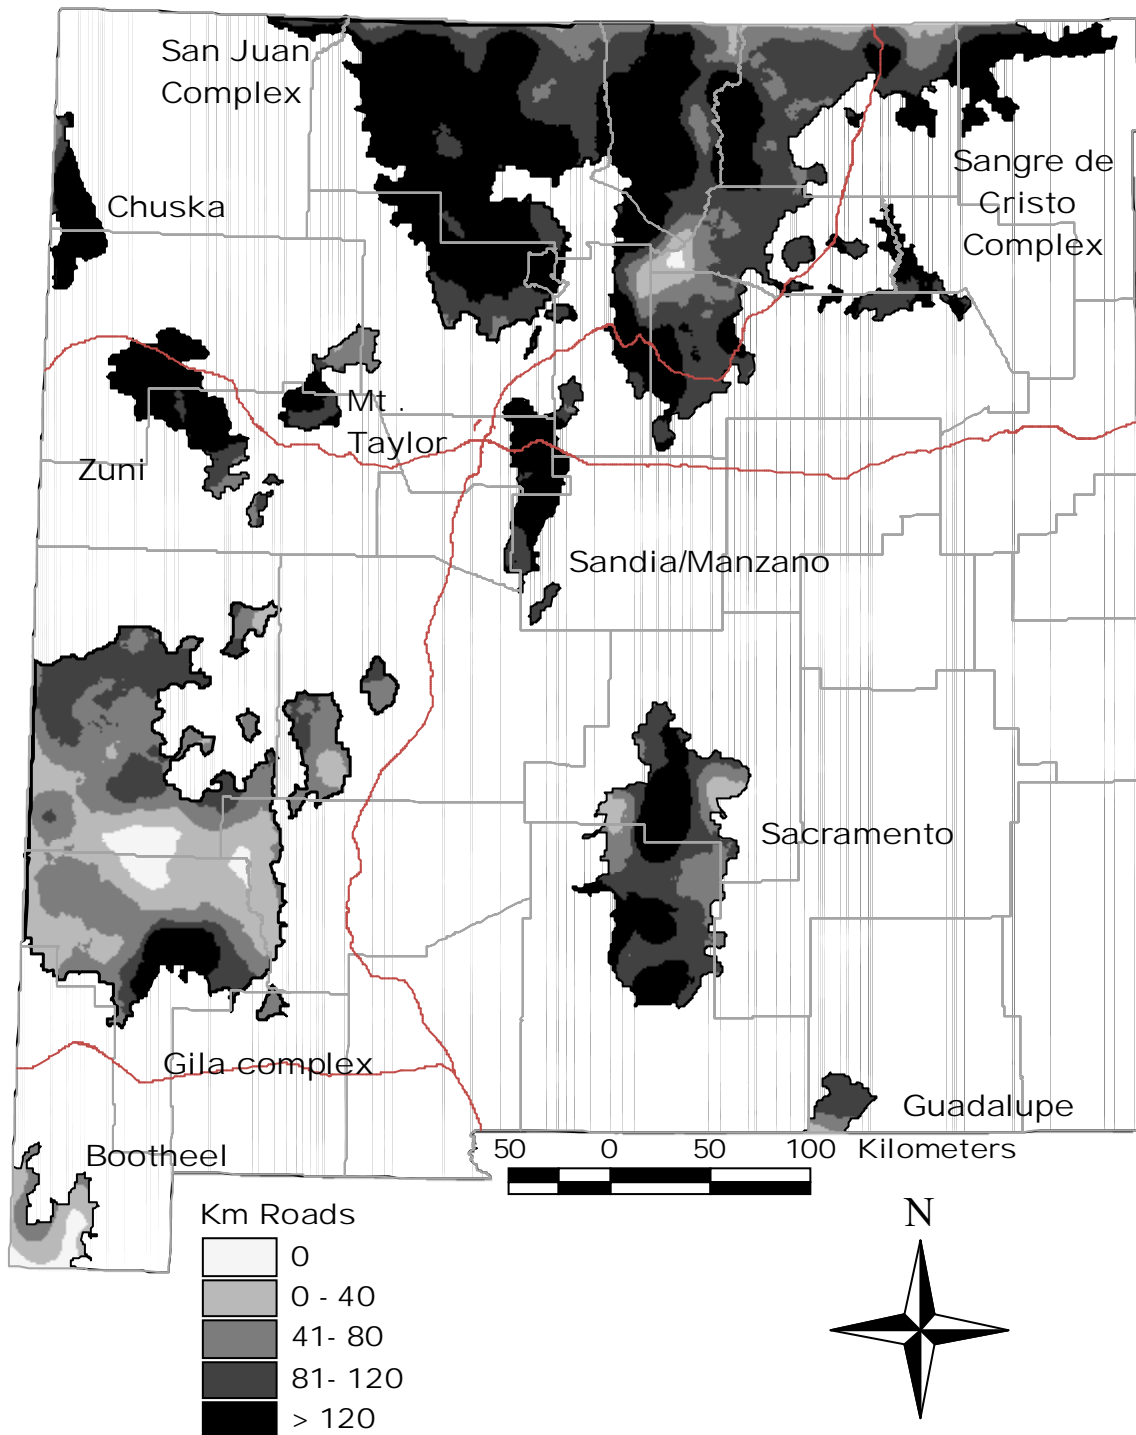

Figure 11-5. Extent of secondary roads within a female black bear fall activity radius (7 Km) in New Mexico.

Relative Extent of Roads within Male Black Bear Fall Activity Radius

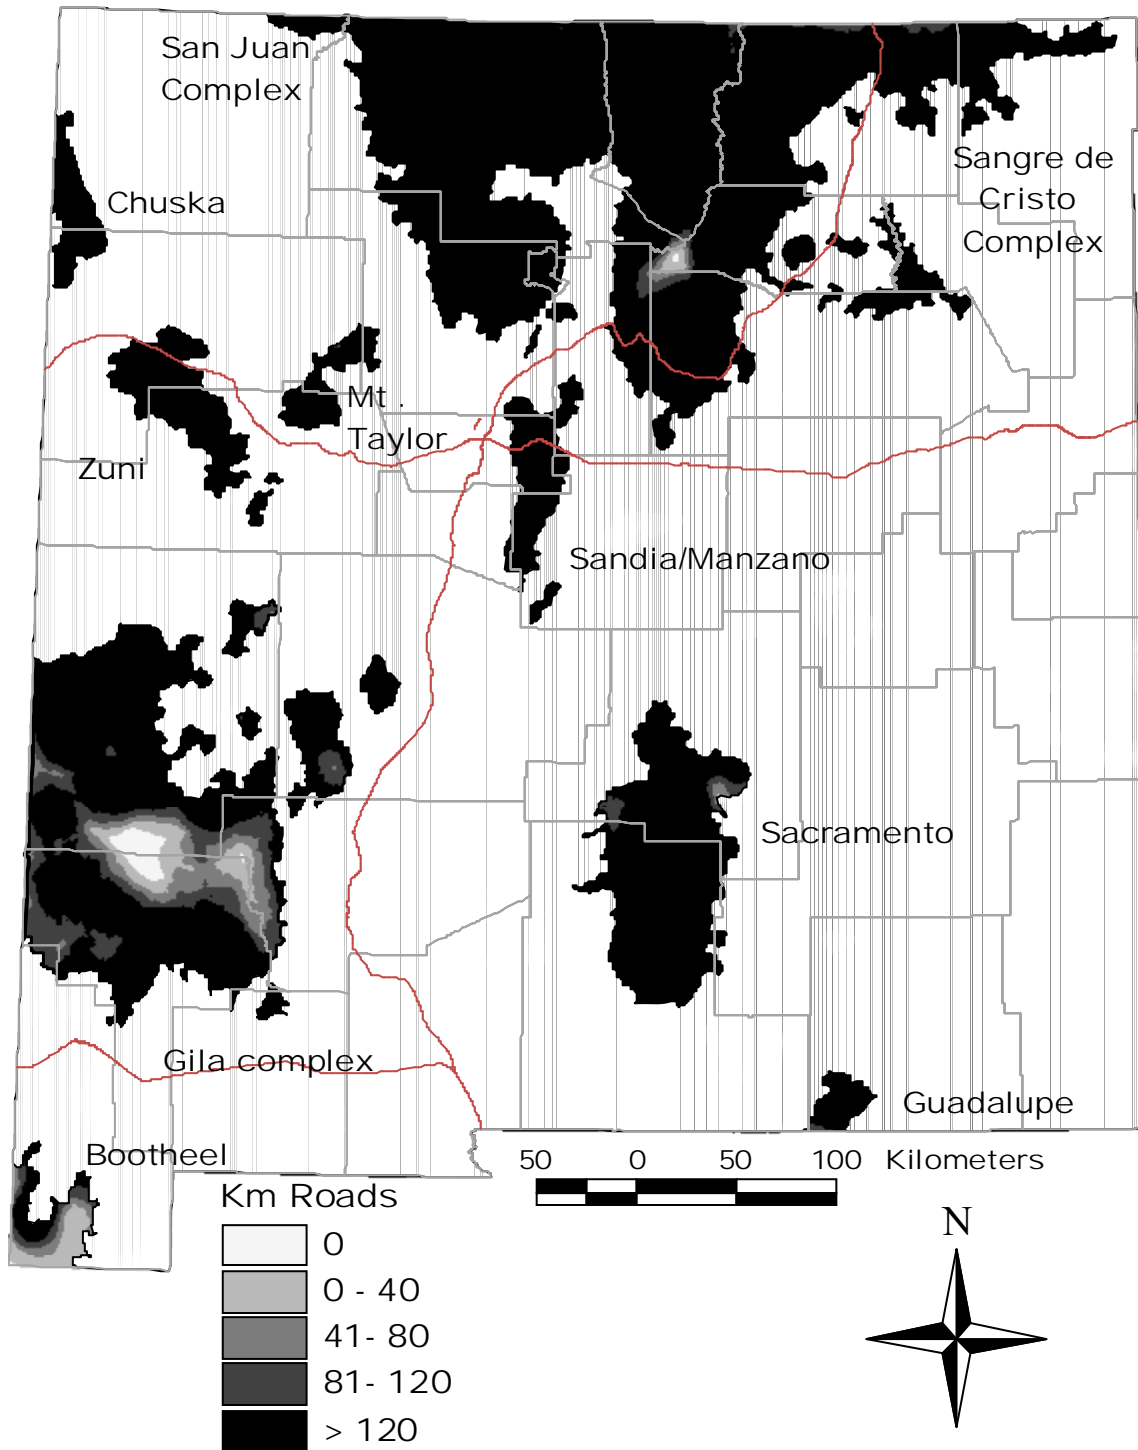

Figure 11-6. Extent of secondary roads within a male black bear fall activity radius (12 km) in New Mexico.

All predicted regions of bear habitat displayed areas that were in proximity to human populations (Figure 11-7). Statewide, 17% of bear habitat was within 5 km of human populated areas. Percent of bear habitat within proximity to human populations differed regionally, with the highest proportions observed in the Sandia/Manzano region, the Sacramento region, and the Sangre de Cristo complex (Table 11-3). Within the Guadalupe region and the Bootheel region, more than 60% of bear habitat was >20 km from human populated areas.

Table 11-3. Percent of predicted suitable black bear habitat within 0 to 20 km of human-populated areas (> 1 person/ha and > 5 households) in New Mexico, based on 2000 U.S. Census Bureau block data and sorted by area of bear habitat.

Region	Area (km ²)	< 5 km	< 10 km	< 15 km	< 20 km	>20 km
Sangre de Cristo	16,960	23.16%	48.77%	66.66%	80.15%	19.85%
Gila	15,472	6.49%	19.69%	36.47%	53.98%	46.02%
San Juan	12,495	14.96%	38.71%	60.96%	75.35%	24.65%
Sacramento	6,642	28.15%	57.50%	74.82%	87.77%	12.23%
Zuni	2,242	17.73%	45.29%	69.15%	86.19%	13.81%
Sandia/Manzano	1,788	50.76%	79.79%	95.63%	98.68%	1.32%
Chuska	1,060	10.30%	43.39%	79.03%	94.64%	5.36%
Bootheel	895	0.89%	4.89%	9.63%	14.18%	85.82%
Mt Taylor	887	1.47%	14.59%	38.16%	60.88%	39.12%
Guadalupe	499	0.10%	5.37%	17.27%	34.38%	65.62%

Predictions for proximity to secondary roads and proximity to human populations did not necessarily coincide. Some areas with relatively higher length of road within activity radii were situated in areas of low human populations, particularly private and USFS lands in the Gila complex and private and tribal lands in the San Juan complex.

Our compilation of various coverages and data sets regarding distribution of human recreation produced information of varied completeness, quality, and spatial resolution. We judged that these data in current form were insufficient to perform detailed analyses relative to distribution of bear habitat and population estimates. Nonetheless, we anticipate that these data, if further compiled with specific objectives in mind, can be used to depict areas of possible human-bear interactions. Thus, we provide these data digitally (see Appendix C) for future users of this report and the associated modeling tools. Those data include consolidated NMDGF hunter and angler survey results for hunt year 1990-1991 through 1999-2000 (hunt year generally is April-March). We were unable to collect spatially explicit results for small game and birds (except turkey). The finest spatial resolution available for all hunts is the GMU. Because some data are missing, care must be taken not to make literal interpretations of absolute hunter days from these data. However, this data set can provide a fair indication of the spatial distribution of hunting activities in New Mexico with further editing.

Distance of Predicted Black Bear Habitat to Human-Populated Areas

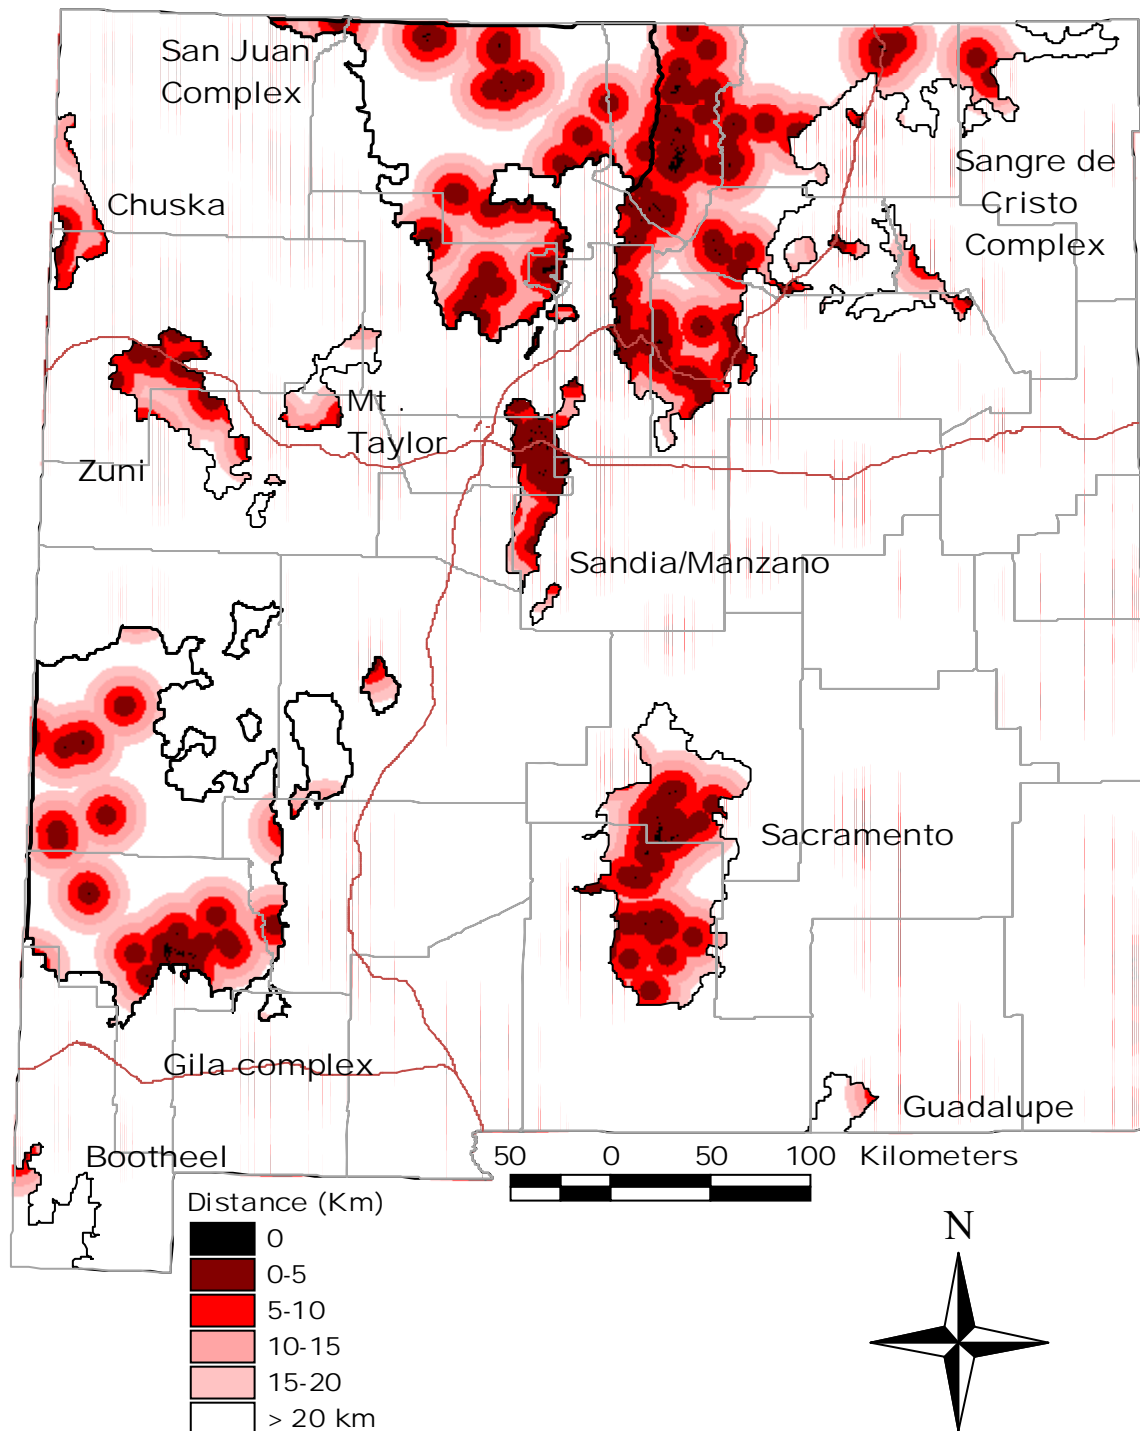

Figure 11-7. Distance of predicted black bear habitat to human-populated areas (>1 person per hectare and >5 households) in New Mexico.

Bear Population Estimate

Extrapolating observed density estimates (see Chapter 10) to areas of primary habitat yielded a statewide population estimate of 5,947 bears >1 year old, pertaining to the premast season (Table 11-2). Regional estimates ranged from 18 bears in the Bootheel region to 2,299 bears in the Sangre de Cristo complex. The small populations (<50 bears) estimated for the Bootheel and Guadalupe regions reflect areas of contiguous habitat with Arizona and Texas

DISCUSSION

In the NMGAP methodology (Thompson et al. 1996), prediction of suitable habitat for a species was based on the premise that a species distribution was all suitable land cover categories within that species general range. Other ancillary variables, such as elevation or soil classification also were included in the habitat modeling when those values were represented on spatially-registered maps. This methodology has proven useful for developing landscape and regional scale maps of species occurrence (Edwards et al. 1996). Another approach is to assign a numeric score to habitat rather than assignment to categories (Boyce and McDonald 1999, Kliskey et al. 1999). In constructing the statewide black bear habitat model for this study, we enriched the modeling process by classifying suitable habitat into multiple categories (e.g., primary, secondary, edge, and no use) rather than the Boolean response (suitable or not) used in NMGAP (Thompson et al. 1996). Our more enriched approach provided greater realism in identifying occupied habitat.

As with all modeling exercises, our habitat prediction results were a compromise between realism, practicality, and data limitations. The largest impediment to a “true” habitat map was the size and scale of this objective. Scaling is probably the most difficult aspect of landscape ecology and the subject of intense research. Large, mobile animals function at a relatively larger scale (Wiens, 1982). Scale is also not independent of spatial pattern (O'Neill et al. 1988). Changing of scale can greatly change perceived landscape patterns. When inappropriate scales are used, true biological relations can become masked or false patterns can emerge (Scott et al. 1996).

Our model was limited to data available as of summer 2001. To our knowledge, NMGAP is the only statewide coverage of land cover (42 themes at 2-100 ha resolution) that exists. There are other vegetation coverages that are more detailed in thematic and spatial resolution but they are not statewide in scope. For example, databases and digital vegetation coverages developed by the USDA Forest Service may provide more comprehensive information appropriate for analysis of black bear habitat quality. Although not statewide, these data would provide insight into a majority of the bear habitat in New Mexico. However, although the data are publicly accessible, at present they are not compiled in a single archive to our knowledge.

Bear reproduction is inherently stochastic with its variability tied to mast crop variability, particularly oaks. Our ability to define this variability statewide was limited because there is no temporal variability in the land cover map. In addition, the land cover map does not differentiate on the basis of subdominant species in each land cover class. Most oak species in New Mexico exist as understory species in several different cover types, therefore the actual abundance of these species cannot be predicted using the current data. Although general predictions of mast potential were developed, more detailed data would be necessary to assess actual habitat productivity between regions.

We were purposely careful to identify suitable habitat and this map should be considered potential habitat rather than actual bear distribution on any given day or in a single year. It is very important to recognize that bears (e.g., transients) can occur in New Mexico outside of the predicted habitat areas. The key consideration is that we modeled conditions on the landscape that are considered to be reliably associated with routine occurrence of reproductively sustaining bear population.

As the human population increases, human-bear interactions have the potential for increase. This raises the value of human-bear interface data. These data serve as a tool to increase the ability of a game/land manager to predict areas of interactions between bears and humans. Spatial data provide a means to “visualize” these areas of interaction on the landscape.

The study area density estimates were derived in productive bear habitat that arguably represents some of the best habitat within their prospective regions. These values may not be applicable to areas of low quality habitat. However, some of this difference was accounted for in the habitat suitability analysis, where secondary habitat was identified. Because the population estimate was derived by extrapolating to primary habitat only, lower quality habitat did not unduly influence the population estimate.

MANAGEMENT IMPLICATIONS

The statewide estimate of 5,947 bears derived from habitat-density extrapolation is similar to the independent estimate derived from population modeling (see Chapter 14). That estimate of 5,200 bears was for the state, excluding the Zuni, Mt. Taylor, Sandia/Manzano, and Chuska regions. Both estimates are for the pre-mast season (May-early August) and excluded cubs of the year.

Statewide population estimates derived from this study refute previous estimates. Our estimates indicate a statewide population of approximately twice the long-standing estimate of 3,000 bears previously used by the NMDGF. However, these estimates do not suggest a doubling of the bear population in the

past decade. Rather, these estimates are based on better information including demographics, density, and habitat extent.

Annual trends in black bear reproductive success were highly influenced by fall mast crops, especially the abundance of acorns. Within predicted bear habitat, mast producing land cover types were found within 7 km (female activity radius) of primary habitat throughout New Mexico except for about 300 km² in the Sangre de Cristo complex. This indicates that nearly all bears have access to habitat with potential for producing important mast producing species. However, the actual abundance of oak, juniper, and pinyon within different regions remains unknown. In the future, incorporation of more detailed data, especially on distribution of oak species, may provide valuable insight into the relative productivity of habitats throughout the regions of New Mexico.

Estimated statewide bear habitat encompasses approximately 14.6 million acres, of which 75% is primary habitat. Primary habitat represents about 13.5% of the state. Approximately 17% of bear habitat is situated within 5 km of human populations. These dimensions clearly illustrate the extent of bear exposure to human influences. More detailed analyses of the dataset provided can be used to target bear conflict and nuisance reduction efforts.

The modeling algorithm is intentionally constructed to alter the criteria so managers can examine different habitat assumptions and land management scenarios. Further, the modeling approach allows incorporation of future, improved spatial data sets (e.g., more resolved land cover) with minimal adaptation or cross-walking of habitat categorizations. Accordingly, it will be interesting and wise to perform sensitivity analyses of conclusions based on this coverage and future modifications.

CHAPTER 12

RELIABILITY OF HARVEST DATA

INTRODUCTION

In New Mexico, as in many states, interpretation of black bear population trend is based primarily on harvest data. Annual harvest data include the total number of hunter-killed bears and sex-age composition in the kill. Given the complexities associated with documenting population trend (Miller 1990, Garshelis 1991), determining the accuracy and consistency of current methods is important.

Age composition of NMDGF harvest data is determined using the cementum annuli aging technique on teeth collected from each bear. This method involves counting the layers of cementum deposited in teeth. Each year, 2 types of cementum are produced which are visible when stained. The first layer is a dark narrow band deposited during the winter months. The second layer appears broad and lightly-stained and is produced during the growth seasons of spring, summer, and fall (Harshyne et al. 1998). When a thin cross-sectional segment of the tooth is viewed, these layers can be counted as an estimate of the animal's age, similar to growth rings on a tree. This method was first developed using canine teeth collected from hunter-killed bears (Sauer et al. 1966, Stoneberg and Jonkel 1966). The technique was further refined by use of the small vestigial premolar tooth, which can be collected from live animals as well as hunter-killed bears (Willey 1974). Accuracy of the cementum annuli aging technique has been tested in only a few locations across North America (McLaughlin et al. 1990, Harshyne et al. 1998). Diet and variability in food supplies are known to affect deposition of cementum layers, therefore accuracy rates from other regions may have no bearing on New Mexico bears. Our objective was to determine the accuracy and consistency in estimating age using teeth from New Mexico black bears. A second objective was to determine the comprehensiveness of the NMDGF harvest data and to document any error with regard to reporting of sex.

METHODS

Harvest-data

We tested the completeness and accuracy of reported sex for the NMDGF hunter-kill (pelt tag) harvest records. These records were tested by comparing them to known hunter-kills of study bears, verified by radio-telemetry monitoring and direct reports from NMDGF personnel.

Cementum Annuli Data

An upper premolar tooth was extracted from most study bears ≥ 1 year of age during initial capture, and a second tooth was collected from some bears during recapture or den investigations, particularly during the final year of fieldwork (see Chapter 4). For hunter-killed study bears, a second tooth also was collected by NMDGF as part of the mandatory check program (see Chapter 11). During 1993, NMDGF personnel removed 2 teeth from each hunter-killed black bear specifically for examining consistency in aging black bear teeth.

All collected teeth, from study bears and hunter-killed bears, were processed by Matson Laboratory (Milltown, Montana) for age determination using cementum annuli counts. Pairs of teeth from the same bears were assigned different numbers to create a blind sample. Date of extraction, sex of bear, and comments relevant to tooth condition (e.g., broken or rotten) were reported to Matson's Laboratory for most tooth samples.

Matson's Laboratory provided us with age estimates with corresponding accuracy limits. These accuracy limits were based on the determined age of the bear and the condition of the tooth sample. In general, they found that error increased with age. Thus, determined ages were grouped into 1-7 years, 8-15 years, and ≥ 16 years. "Certainty codes", based on tooth condition, were superimposed on these age groupings. Assigned certainty codes were (A) result nearly certain, (B) some error possible, and (C) error likely. The combination of the tooth age grouping and the certainty code resulted in an age estimate with a corresponding range of error in years.

We tested the consistency of the aging technique by comparing 2 or more age estimates obtained for a single individual. Two samples were used for consistency analysis: (1) paired teeth collected from hunter-killed bears on the same day, and (2) pairs of teeth collected from study bears on different dates (often years apart). We tested accuracy of the aging technique by obtaining age estimates from known-age study bears. The sample of known-age bears consisted of individuals handled as cubs or yearlings in the den, and individuals confidently aged from tooth eruption when captured as cubs or yearlings.

Using Chi-square tests and Pearson's correlation, we evaluated consistency relative to estimated age class (or mean age class of pairs), sex, tooth condition, certainty code, and season of extraction (den = January-April, active = May-October). Probability levels are reported for all test outcomes reported.

RESULTS

Harvest Data

From 1992-1999, 42 marked study bears were known harvested by hunters, including 16 radio-transmitted bears and 26 marked bears. Three bears (7%) were not included as records in the NMDGF harvest database. In all instances, the bears were known to have been checked by a NMDGF officer, however record of the kill was not present in the central database. Sex was accurately recorded for all study bears present in the harvest database.

Cementum Annuli Aging

Age estimates were obtained for 236 pairs of teeth collected by NMDGF personnel in 1993. All teeth were collected during the mast season. Most age estimates (83%, $n = 472$) were assigned a certainty code of A (result nearly certain), while 16% were assigned as B (some error possible) and 1% were assigned C (error likely). Among the 96 teeth that were broken (20% of total), most were assigned a certainty code of B (61%), while 32% were assigned as A and 6% were assigned as C.

Teeth were consistently aged for 74% of pairs ($n = 236$). Among pairs inconsistently aged ($n = 96$), discrepancies ranged from 1-6 years, with a mean of 1.6 years. Percent inconsistency among pairs differed by certainty code ($X^2 = 28.7$, $df = 2$, $n = 236$). Among pairs with both age estimates assigned A, 83% of pairs were consistently aged ($n = 168$). Only 52% and 33% of pairs were consistently aged when ≥ 1 assignment was B ($n = 62$) or C ($n = 6$), respectively.

Discrepancy in estimated age, in years, was positively associated with mean estimated age of the pair (Pearson $r = 0.51$, $P = 0.001$, $n = 236$). Compared to intermediate groups, percent inconsistency was significantly lower (9%) for pairs with a mean estimated age of 1 and significantly higher (46%) for pairs with a mean estimated age of ≥ 5 ($X^2 = 34.7$, $df = 4$, $n = 236$).

Percent consistency also was lower when teeth were broken (50% vs. 83%, $X^2 = 27.8$, $df = 1$, $n = 236$), however percent tooth breakage was positively associated with estimated age class ($X^2 = 29.3$, $df = 5$, $n = 472$) and with higher certainty codes ($X^2 = 214.4$, $df = 2$, $n = 472$). Only 8% of ages designated with A ($n = 392$) were broken, while 88% and 100% of ages designated with B ($n = 62$) or C ($n = 6$) were broken.

Percent consistency differed by sex ($X^2 = 6.6$, $df = 1$, $n = 231$). Percent consistency was 65% for females and 80% for males. However, mean estimated age of tooth pairs was higher for females than for males ($t = 4.8$, $df = 174$, $P < 0.001$, $n = 231$).

Extraction of improper teeth (e.g., molars, incisors) did not appear to affect consistency, however sample size was very low. Inconsistency in estimated ages was 33% for these teeth ($n = 6$), however the patterns of inconsistency relative to estimated age and certainty codes appeared similar to other teeth.

The observed inconsistencies in aging did not appear to affect the estimated age composition of the harvest (Table 12-1). Comparing the 2 blind samples (obtained independently), estimated age composition of the harvest did not differ statewide ($\chi^2 = 1.4$, $df = 5$, $P = 0.92$, $n = 472$) or for any region ($P \geq 0.55$).

Table 12-1. Estimated age composition of hunter-killed black bears, by region, using the cementum annuli technique applied to 2 blind samples of premolar teeth in New Mexico, 1993.

Region	Sample	n	Percent composition by age category ^a					
			Cub	1 year	2 years	3 years	4 years	≥ 5 years
Statewide	1	236	0	14	26	13	5	42
	2	236	0	14	28	12	6	41
San Juan complex	1	55	0	11	26	18	7	38
	2	55	0	13	24	18	11	35
Sangre de Cristo complex	1	77	0	14	22	9	3	52
	2	77	0	14	23	8	3	52
Zuni and Mt. Taylor regions	1	20	0	10	20	0	0	70
	2	20	0	10	20	10	0	60
Sandia/Manzano region	1	10	0	20	0	0	20	60
	2	10	0	20	0	0	20	60
Gila complex	1	29	3	14	35	14	3	31
	2	29	0	17	35	14	3	31
Sacramento region	1	56	0	16	29	14	5	36
	2	56	0	14	34	11	5	36

^a Percent composition did not differ between samples for any region ($P \geq 0.55$).

We obtained age estimated for 61 pairs of teeth from study bears (actual ages not known). Most age estimates (85%, $n = 122$) were assigned a certainty code of A, while 11% were assigned as B and 3% were assigned C. Among the 20 teeth that were broken (16% of total), most were assigned a certainty code of A (80%), while 10% were assigned as B and 10% were assigned as C. Pairs of teeth were extracted 0-9 years apart, with a mean of 4.0 years ($n = 61$).

Teeth were consistently aged for only 46% of pairs ($n = 61$). Among pairs inconsistently aged ($n = 33$), discrepancies ranged from 1-12 years, with a mean

of 2.8 years. Percent inconsistency among pairs did not differ by certainty code ($X^2 = 1.0$, $df = 2$, $n = 61$). Discrepancy in estimated age, in years, was positively associated with mean estimated age of the pair (Pearson $r = 0.50$, $P < 0.001$, $n = 61$).

Percent consistency was lower when teeth were broken (46% vs. 80%, $X^2 = 5.4$, $df = 1$, $P = 0.04$, $n = 61$), however percent tooth breakage was positively associated with higher certainty codes ($X^2 = 21.9$, $df = 3$, $n = 122$). Only 13% of ages designated with A ($n = 103$) were broken, while 21% and 100% of ages designated with B ($n = 14$) or C ($n = 4$) were broken. Percent consistency was lower for tooth pairs when 1 or both teeth were removed in the den (34% vs. 62%, $X^2 = 4.5$, $df = 1$, $P = 0.04$, $n = 61$). Percent consistency did not differ by sex ($X^2 = 1.0$, $df = 1$, $P = 0.40$, $n = 61$).

For 26 of 31 (84%) inconsistent pairs of teeth extracted during different years, the age estimate from the tooth extracted at an older age was lower than the age estimate for the tooth extracted at a younger age (accounting for the difference in years). In other words, compared to earlier ages estimated, older ages were underestimated most of the time.

Accuracy Analyses

We obtained age estimates for 29 known-age bears, including 15 yearlings, 10 subadults, and 4 adults. Twenty-eight of 29 age estimates (97%) were assigned a certainty code of A, and 1 age estimate (3%) was assigned B. No teeth were broken among this sample.

Most of these teeth (83%) were accurately aged ($n = 29$). Among age estimates designated with A, 86% were accurate, but the single age estimate designated with B was inaccurate. Difference between estimated age and actual age ranged from 1-2 years, with a mean of 1.2 years ($n = 5$). All inaccurate age estimates were underestimates.

Percent accuracy differed by age class ($X^2 = 6.9$, $df = 2$, $P = 0.03$). All yearlings were aged accurately, while 60% of subadults and 75% of adults were aged accurately. Percent accuracy did not differ by sex ($X^2 = 0.08$, $df = 1$, $P = 1.0$).

Accuracy of age estimates differed by season ($X^2 = 13.4$, $df = 1$, $P = 0.001$). Estimates from teeth extracted during the active season were 100% accurate, while estimates from those extracted during the den season were only 55% accurate, however only sub-adult and adult teeth were extracted during the den season.

DISCUSSION

Harvest Data

Results revealed both negative and positive aspects regarding usefulness of the harvest data obtained by the NMDGF. Our analyses indicated the harvest data were incomplete, underestimating the annual bear kill by as much as 7%. This proportion not only limits the usefulness of these data for monitoring total kill, but also hinders reliable estimation of sex-age composition of the kill.

On the other hand, analyses indicated age estimates using the cementum annuli method were relatively accurate and consistent for New Mexico bears. Accuracy and consistency were negatively associated with age and tooth breakage, however these 2 factors were correlated. These results supported earlier findings that consistency and accuracy declined with age (Willey 1974, McLaughlin 1990, and Harshyne et al. 1998). Sauer et al. (1966) suggested cementum annuli were more difficult to count in older teeth because annuli become thinner as the tooth ages.

Differences in the patterns of annuli deposition have been noted for male and female black bears (Coy and Garshelis 1992). Cross-sections of male teeth have displayed dark accessory lines that can be confused with annuli, especially in late summer and fall. On teeth from female bears, narrow bands associated with cub rearing can make distinction of adjacent annuli difficult to observe, leading to miscounts. Despite these potential differences, our analyses did not indicate sex affected accuracy or consistency of aging, and these findings were consistent with Harshyne et al. (1998). Although female teeth were less consistently aged in the sample of study bears, evidence indicated age was the factor likely causing the difference.

Accuracy and inconsistency were also affected by season. Age estimates from teeth extracted in the den were less consistent than those from teeth extracted during the active season. When the den-extracted teeth were removed from the known-age sample, accuracy improved to 100%. This may have been due to the fact that black bears deposit annuli during the winter and new annuli may not appear visibly until late spring (Sauer et al. 1966, Coy and Garshelis 1992).

MANAGEMENT IMPLICATIONS

Accuracy and consistency of the cementum annuli method appeared adequate for estimating age of New Mexico black bears. Among adult bears, our findings indicated the cementum annuli method was not precise enough to identify specific age cohorts. However, accuracy and consistency was relatively high for bears with known or estimated ages <5 years old. Identification of specific cohorts is only required for these younger age classes, therefore the

method appeared adequate to classify bears into age classes and to estimate the age composition of the kill.

According to Matson Laboratory, 2 types of tooth breakage occurred. The first occurred when the root tip was broken off during extraction. The second occurred when the tooth was removed intact, but the tools used for extraction damaged the cementum annuli. Breakage probably cannot be completely avoided, especially when extracting teeth from older bears. However, extra care in tooth extraction, use of proper tools, and improved training of personnel responsible for tooth extraction will aid in the consistency of aging teeth.

CHAPTER 13

PATTERNS IN HARVEST DATA

INTRODUCTION

New Mexico has more than 2 decades of black bear harvest data, a rich information resource. Harvest data document harvest numbers and provide a historical perspective on new information accumulating year by year. Relationships among harvest, regulations, effort, and environmental conditions provide valuable insight for managers that is useful for regulating harvest numbers and composition.

Black bear harvest data alone do not provide a window onto populations; changes in harvest size and composition do not indicate trends in the living resource population (Garshelis 1990). This study provides an opportunity for limited comparisons of live populations and harvests.

Our objective in this chapter is to describe relationships between the harvest sample and the sex-age composition of study populations. We do this from the standpoint of hunter supplied information, kill records, and results of field investigations.

METHODS

Harvest Data

Tagging of bear pelts and reporting of all hunter-killed bears has been mandatory in New Mexico since 1978. NMDGF officers have recorded proof of sex and collected a tooth for estimating age of bears since 1985. Other information recorded included date and Game Management Unit (GMU) of kill, use or nonuse of dogs, and use or nonuse of guides. Pelt tag records were complete through 1999.

A card survey has been mailed to all licensed bear hunters with usable mailing addresses since 1990. Information requested included whether they hunted, used guides or used dogs, days hunted in up to 3 different GMUs, killed a bear, and sex and GMU location of kill. Statewide effort and success projections by hunt method were based on individual responses with use or nonuse of guides and dogs reported. For the 1994 survey, use of guides and use of dogs could not be separated, so projections were made for using aids (guides or dogs or both) and no aids (neither).

Hunt regulations and license costs were obtained from annual NMDGF Proclamations. Numbers of licenses sold were obtained from NMDGF fiscal records.

Regional summaries were compiled for contiguous game management units including mountain ranges. The Gila complex, containing the SSA, consists of GMUs 13, 15-17, 21-24, 26, and 27. The Sangre de Cristo complex, containing the NSA, consists of GMUs 41-49 and 53-58.

Years in summary tables are calendar years of hunting seasons, not fiscal year or license year designations. Harvest numbers in summaries are derived from pelt tag reports, considered more reliable than projections from the hunter card survey. Correlation coefficients were calculated from annual statewide total harvest numbers and license sales.

Effort, Success, and Hunting Method

Estimates of hunter success were based on reported numbers of hunters and kills by GMU from card survey returns for each year. Hunters reporting days in multiple GMUs were included in each unit reported. Unit hunter and bear harvest numbers using guides, dogs, both, or neither, were summed over GMUs for regional totals. Success by year and method was calculated as total reported harvest divided by total reported hunters for each region.

Proportions of hunters or harvests by hunting method were based on the subset of records with hunting methods known. Numbers of hunters or harvests by hunting method were calculated as the product of total hunters or harvests and calculated proportions. Most pelt tag and hunter card survey records contained information on hunting methods used.

Regional harvests and resident study populations were compared for 1993-1997; later years are excluded because hunt regulations and effort changed substantially in 1998, potentially confounding any change in the relationship of live and harvest sample composition. We looked at age composition of females only, because reproductive females are important to population trends, and migrant subadult males may confound male age structure and sex ratios. Study area live population proportions were recalculated excluding cubs, because cubs do not appear in harvest data. We examined proportions of yearlings of all females, yearlings and subadults of all females, and subadults of all females aged ≥ 2 years.

Years of mast failure were determined from combined oak mast index measured on the study areas (see Chapter 5).

Age and Sex Composition

Ages of hunter-killed bears were based on cementum annuli analysis of collected teeth (see Chapter 12). Age class proportions were calculated only from records with age estimates. For total numbers by age class, the un-aged subset was prorated among age classes using the proportions derived from the aged subset for each sex. Most pelt tag records had associated age estimates. Year of birth for hunter-killed bears was calculated from age estimates. Virtually all pelt tag records included sex of kill.

Age and sex composition of study area live populations was based on population reconstructions (see Chapter 10). Year of birth for study area bears aged ≥ 1 year was known from den observations or calculated from tooth age estimates. Sex was known for all study area bears.

Relative numbers of bears by year of birth were compared for the study area populations and hunter-killed bears from the surrounding regions. From live population data, bears were counted by cohort year. All study bears observed at age ≥ 1 were included, regardless of age at first observation, date of capture, or den observation. Individual study bears were counted only once, regardless of frequency of observation. For harvest data, bears from a cohort year were represented by kills during the 3 hunt years following the birth year of the cohort. Proportions of 1, 2, or 3-year-olds of all-aged hunter-killed bears were calculated for the appropriate hunt year, to eliminate distortion from annual variation in total harvests. An index of harvest abundance for each cohort was calculated as the sum of its representative year class proportions at ages 1-3. For example, the index for bears born in 1991 was the sum of the proportion of 1-year-olds in the 1992 harvest, 2-year-olds in the 1993 harvest, and 3-year-olds in the 1994 harvest.

RESULTS

Patterns in Harvest, Effort, and Success

Statewide bear harvest fluctuated (Figure 13-1). The largest annual number of hunter kills for both sexes was reported in 1994, with declining numbers in each of the following 4 years. Year to year variation in statewide harvest numbers was similar for the sexes. Detailed statewide and regional information from pelt tag reports and card survey projections is presented in the Pelt Tag Notebook (Appendix D) that describes black bear harvest data history through 1999. Fall and spring hunts occurred in New Mexico from 1978-1991. Early fall hunts, beginning by 1 September and ending 31 October, occurred from 1992-1997. Late fall hunts, beginning 1 or 15 October and ending 15 December, occurred from 1998-2000.

Figure 13-1. Numbers of black bear hunting licenses sold and pelt tags reported in New Mexico for years with both spring and fall hunts (1978-1991), early fall hunts only (1992-1997), and late fall hunts only (1998-2000).

License sales and statewide harvests increased during the 1990s (Table 13-1). Average license sales and average total females harvested for 1990-2000 were 38% greater than for 1983-1989. Because of the peak harvest in 1994, average harvests increased out of proportion to license sales for 1994-1997 compared to previous 4-year averages, both regional and statewide. Average harvests decreased for 1998-2000 because of the shift to late fall hunt dates.

Table 13-1. Average license sales and harvest reports for female (F) and male (M) black bears in New Mexico for 1978-2000.

^b averaged over 1983-1985

Bear hunters in New Mexico consistently harvested more males than females (Table 13-2). The female proportion of annual statewide harvest ranged from 29 to 46%. The proportion of females averaged 37% during the years of combined spring and fall hunts, 41% during early fall hunts, and 36% for late fall hunt years.

Harvest patterns differed by region (Figure 13-2). Harvests in the Gila and Sangre de Cristo complexes fluctuated, but Gila numbers were more variable. The 1994 female harvest in the Gila complex was 4 times the average from previous years, and more than twice the harvest from any other year. In contrast, Sangre de Cristo regional female harvests were elevated for 1993-1995, at about twice the average from previous years.

From 1983-2000, annual statewide license sales varied more than 2-fold (Appendix D, Table 2). License sales decreased in years with regulation or cost changes. License sales dropped 36% and total black bears harvested dropped 11% in 1986, when spring season dates were shifted 1 month earlier and the fall season was closed during elk firearm hunts. License sales decreased 59% and total harvest decreased 17% in 1992, when spring hunting was discontinued and

the fall season was shortened to September and October only. License sales decreased 35% and harvest decreased 25% in 1996, when license cost for residents increased from \$10 to \$30. License sales decreased 22% and total harvest decreased 52% in 1998, when the fall season dates were shifted 6 weeks later and no licenses were sold after the hunting season began.

Table 13-2. Numbers and mean ages of female (F) and male (M) black bears harvested statewide and in 2 regions of New Mexico where study areas were located, 1985-1999.

Year	Statewide				Sangre de Cristo complex				Gila complex

1998	51	97	5.3	4.4	20	50	5.8	4.0	10	12	7.4	7.4
1999	60	150	6.1	4.5	20	59	5.4	5.8	14	26	7.1	2.4

Total hunt effort influenced total harvest. Correlations between statewide annual total legal kills and total licenses sold were 0.68 for 1983-1991 with both spring and fall seasons, 0.82 for 1992-1997 with early fall seasons, and 0.90 for 1998-2000 with late fall seasons.

Success rates for all black bear license buyers were relatively low, ranging from 5-9% for years with spring and fall hunts, from 7-10% for early fall hunts except for 13% in 1994, and from 4-6% for late fall hunts. The exceptional success rate in 1994 coincided with the largest statewide annual harvest.

Figure 13-2. Number of female hunter-killed black bears reported from the Gila and Sangre de Cristo complexes of New Mexico, 1978 – 2000.

Patterns by Hunting Method and Season Timing

Hunters using dogs were about 3 times as successful as hunters not using dogs (Table 13-3). Using dogs doubled success for unguided hunters, and increased success 2 to 5 fold for guided hunters. Using dogs increased success more in spring and late fall hunts than in early fall hunts.

Table 13-3. Average annual participation and hunter success by hunting method and season timing from card survey data and pelt tag reports from black bear hunting in New Mexico, 1990-1999.

	Hunt season timing			
	Spring 1990-1991	Early fall 1990-1993 1995-1997	Early fall 1994	Late fall 1998-1999
Comparison by hunting method				
Percent of hunters using each method, from hunter card survey				
Guides and dogs	17	8		7
Guides only	2	4		10
Dogs only	19	10		10
Neither	63	78	73	74
Percent success by method, from hunter card survey				
Dogs	22	28		21
No dogs	3	9		6
Percent of females in harvest by method, from pelt tag reports				
Dogs	23	46	40	35
No dogs	22	37	43	30

Fall season hunters using dogs took a higher proportion of females than hunters not using dogs, except for 1994 when hunters not using dogs took an unusually high proportion of females (Table 13-3). Hunters using dogs took about 4 times as many female bears per hunter as hunters not using dogs (Table 13-4).

Most hunting effort was without dogs (Table 13-3). In fall hunts, an average of 18% of all hunters used dogs; in spring, 36% used dogs. However, hunters using dogs took 45% of the female bears killed during fall hunts and 71%

of the few females killed during spring hunts, because of higher success rates and higher percentages of females taken with dogs.

The proportion of females in early fall hunter kills was double that in spring kills. Overall, 41% of early fall harvests, 32% of late fall harvests, and 21% of spring harvests were female. The same pattern held for all hunting methods (Table 13-3).

For all hunting methods, success rates were higher for early fall hunts than for late fall or spring hunts (Table 13-3). Overall success from card survey reports was 13% for early fall hunts (except for 1994 with 48% success reported), 11% for spring hunts, and 9% for late fall hunts.

Table 13-4. Relationships of hunting method and season timing to female black bear harvest in New Mexico, 1990-1999.

Comparison by hunting method	Hunt season timing

No dogs	29	54		55

Patterns by Mast Availability

The NSA did not experience a mast failure during the late fall season hunt years 1998-2000, and experienced only a single year of mast failure during the early fall hunt season years from 1993-1997. The SSA experienced mast failure in 2 of the 5 early fall hunt season years and in 2 of the 3 late fall hunt season years.

In the Gila complex, more bears were killed in years of mast failure during early and late fall seasons (Table 13-5). This pattern was observed with or without guides and dogs. In the Sangre de Cristo complex early fall hunts, the proportion of females in the total harvest was higher during the mast failure year. In the Gila complex, hunters using dogs or guides killed the same proportion of females in mast failure years as other years. However, on average 78% of the hunting effort in the Gila complex was by hunters not using aids, who took a higher proportion of females in mast failure years. Statewide, the largest bear harvest in early fall hunts occurred in 1994, and the largest harvest in late fall hunts occurred in 2000, both probably years of widespread mast failure.

Table 13-5. Hunter success, sex composition, and total harvest of black bears in New Mexico by hunting method for years with and without mast failures, 1993-1999.

Parameter by hunting method	Early fall hunts				Late fall hunts

For the Gila complex, the contrast in average harvest was exaggerated by an exceptionally high harvest in the mast failure year 1994 (with 242 bears reported), and an exceptionally low harvest in the non-failure year 1998 (with 22 pelts reported) when regulations changed significantly and effort and harvest decreased statewide.

Live Population and Harvest Age Composition

More individual bears born in 1991 were captured on both study areas than bears born in 1990 or 1992; bears born in 1988-1990 were observed less frequently than those born in 1987 or 1991. A similar pattern occurred in hunter-killed bears from the surrounding regions (Figure 13-3). The 1994 cohort in the SSA and Gila region, and the 1995 cohort in the NSA and Sangre de Cristo complex, were relatively small in harvests and live captures. No yearlings were observed in dens from the 1992 and 1994 cohorts on the NSA, and only 1 yearling was observed from the 1993-1995 cohorts on the SSA (Table 13-6).

Table 13-6. Yearlings per adult female (F, aged ≥ 5 years) from den observations on the Northern Study Area (NSA) and Southern Study Area (SSA) in New Mexico, 1993-2000.

Year of observation	Cohort year	NSA		SSA	
		No. adult F dens observed	Yearlings / adult F	No. adult F dens observed	Yearlings / adult F
1993	1992	5	0		
1994	1993	8	0.63	6	0
1995	1994	12	0	9	0.11
1996	1995	16	0.63	15	0
1997	1996	23	0.22	15	0.67
1998	1997	27	0.48	18	0.33
1999	1998	23	0.59	19	0.58
2000	1999	21	0.52	16	0.56

In both live study populations, adults comprised 54% of resident females ≥ 1 year old on average (Table 13-7). Adults comprised 58% of female harvests in the Sangre de Cristo complex and 70% of female harvests in the Gila complex on average for 1993-1999 (Table 13-7). Both live populations averaged 65% females of all resident bears, with little annual variation, from 1993-1999.

Regional harvests varied from 26 to 48% females in the Sangre de Cristo complex, and from 31 to 48% female in the Gila complex.

Figure 13-3. Relative numbers of black bears born in the indicated years and subsequently killed by hunters at ages 1-3 in the Sangre de Cristo and Gila complexes of New Mexico, 1985-1999, or captured live at any age on the New Mexico black bear study areas within the regions, 1993-1999.

Yearling proportions of females were higher in study area live populations than in early fall season harvests from the surrounding regions. From 1994-1997 subadults comprised 42% of live population resident females aged ≥ 2 years on the NSA and 44% on the SSA. In contrast, subadults comprised 38% of reported female hunter kills aged ≥ 2 in the Sangre de Cristo complex, but only 27% in the Gila complex, during the same years. In 1993, the NSA live population had 43% subadults, but the Sangre de Cristo harvest had only 24%; both SSA and the Gila harvest had 44% subadults.

Table 13-7. Proportions of adults (≥ 5 years old), subadults (2-4 years old), and yearlings (1 year old) in black bear harvests from the Sangre de Cristo and Gila complexes of New Mexico, 1993-1999.

DISCUSSION

Harvest Patterns

In 1994, statewide harvest jumped to a record peak, and then dropped steadily during the following 4 years. Harvests for 1994-1998 differed from the fluctuating, but gradually increasing, pattern of harvests from previous years. Such a dramatic change should get the attention of managers. We cannot determine from harvest data alone whether the 1994-1998 numbers reflect overharvest and subsequent population decline. Examination of factors associated with the pattern can illuminate the information that is embedded in harvest data.

Higher harvests in the 1990s than the 1980s were associated with increased license sales. The record harvest in 1994 was not a statewide phenomenon, but derived from an anomalous harvest from the Gila complex, large enough to affect the statewide total. Return to a normal harvest size in the Gila complex in 1995 accounted for most of the decrease in statewide harvest for that year. License sales were lower in 1996-1997 than in 1994-1995, probably accounting for some of the reduction in total harvest. The decrease in statewide harvest in 1998 likely resulted from a change in hunt season from early to late fall, and an associated reduction in license sales. While these observations do not rule out a population change as the reason for decreasing bear harvests, they do suggest reasonable alternative explanations.

Harvest data history for the Gila complex implied that the impact of the 1994 hunt on the black bear population was unusual, but its effect on the population trend is not known. The high number of females removed from the population is a significant management consideration. The harvest data can provide useful indicators for managers, even without providing certainty about populations.

Why was the 1994 harvest in the Gila complex so large? Regional hunter numbers were not unusual, but success rates were extraordinary. Cub survival on the SSA was very low in 1994, and many adult females may not have been accompanied by cubs, thus not protected from hunting. Oak mast failed in 1994, and a dry summer and wildfires may have increased food stress. Bears moved longer distances during years of oak failure (see Chapter 9), and may have been more likely to encounter hunters as a result. Average annual harvest totals, hunter success rates, and percent of females harvest by unaided hunters were higher in years of oak mast failure in the Gila complex during both early and late fall hunt seasons. The proportion of females in the total harvest was also higher during the mast failure year in the Sangre de Cristo early fall hunts. Hunter success, percent of females in the kill, and mean age of females killed were inversely related to fall food abundance in Minnesota (Noyce and Garshelis 1997). Higher harvest levels also were associated with shortages of natural foods in Massachusetts (McDonald et al. 1994).

Patterns of harvest over time differed by mountain range region for New Mexico. Environmental conditions may not be uniform statewide in any given year. Harvest data should be examined by region, and regional differences in management objectives and strategies are appropriate.

The timing of hunt seasons influenced the size and composition of the harvest. Early fall hunts in New Mexico resulted in higher effort, success, and proportion of females in the harvest compared to late fall or spring hunts, and produce larger total harvests and female harvests.

Hunters using dogs harvested more bears per hunter, and proportionally more female bears, than hunters not using dogs. Most hunters in New Mexico did not use dogs. In early fall hunts, about 20% of hunters used dogs, but took almost 50% of the females harvested. The influence of hunting method on harvest depends on the combination of effort, success, and proportion females taken by different hunting methods, and is not simple to predict.

Live Population and Harvest Comparisons

In the study design, we planned to relate the live population sample represented by study bears to the killed sample represented by harvests, to explore what harvests could indicate about populations. This proved difficult in practice. Ideally, the size and composition of harvests from the study populations would be compared to the size and structure of the study populations over time. However, too few study bears were killed by hunters for meaningful comparisons.

As an alternative, harvests from the mountain range regions surrounding the study areas were used for the killed samples. The study area populations were used to represent the population structures for the larger regions, a problematic assumption. The unhunted status of the NSA during much of the study weakened its comparison with the hunted Sangre de Cristo complex. During the record high 1994 harvest in the Gila complex, no SSA hunting mortalities were observed, suggesting that hunting on the study area was not typical of hunting in the larger surrounding region. These limitations apply to the remaining discussion.

Relative Cohort Sizes

Examination of year classes of hunter-killed bears over time revealed striking and persistent differences in relative numbers by year of birth. Some cohorts were virtually absent from the harvest records. Bears born in 1988-1990 were relatively scarce in New Mexico harvest data, reflective of the decrease in proportion of subadults in the early 1990s and part of the concerns that prompted this study.

Age distributions from harvests (killed samples) and study area captures (live samples) showed similar variation in apparent cohort size from year to year (Figure 13-3). Because live captures began in 1993, cohorts born in earlier years were represented on the study areas only by older survivors and residents, and more recent cohorts were exaggerated in number compared to earlier ones in the live samples. Because harvest age collection began in 1985, pelt tag records contained information on cohorts born since 1984.

Apparent cohort size variation suggested underlying reproductive variation. A pattern of alternating larger and smaller cohorts appeared in the harvest data for the 1980s and 1990s, and from the live sample for the 1990s, consistent with moderately synchronized reproduction. In both the NSA and SSA samples, the alternating year pattern failed in 1989, with a small cohort where a larger one would be expected. The cohorts from 1988-1990 were smaller than the 1987 and 1991 cohorts. This combination suggested that bear reproduction may have been lower than normal during the late 1980s.

Correspondence between apparent relative cohort size and natality can be examined for the years of the study. The 1992 NSA cohort and the 1993 SSA cohort were missing in den observations (Table 13-6) but not in study live captures or regional harvests. The discrepancy may be attributable to the very small sample sizes for natality observations for the first year on each study area. Cohorts on the NSA from 1994 and 1996 appeared small relative to 1993 and 1995 in den observations, live captures, and harvests. The same was observed for cohorts on the SSA from 1994 and 1995 compared to 1996. For years with higher sample sizes, study natality data were consistent with apparent cohort size differences in the harvest.

The relative proportions of bears from different birth years in harvest data appeared to reflect the relative proportions of bears from different birth years in the study area live populations. The patterns of variation do not imply the causes of variation. Cohorts may appear relatively large when they are not absolutely large if mortality in adjacent cohorts was high. But absence of a cohort in harvest records for several years may indicate low reproductive success for that birth year. A missing cohort is a flag indicating possible poor reproduction; other evidence such as associated mast abundance must be considered. Missing cohorts in harvest data records are more useful for interpreting historical records than for evaluating current populations, because several years of data collection are needed to detect the differences in cohort representations in the harvest.

MANAGEMENT IMPLICATIONS

Harvest patterns and environmental conditions differ among mountain range regions in New Mexico. Analysis of harvest data and related factors on a regional basis is appropriate.

Changes in black bear populations cannot be detected from harvest data alone. However, patterns in harvest data may flag areas of concern to managers. Missing cohorts and associated decreases in proportions of subadults in the harvest over several years suggest poor reproduction. Other evidence such as mast availability should be examined, and the possible population consequences can be factored into management considerations.

Hunting method appears to affect proportion of females in the kill. During 1990-1999, hunters using dogs were 3 times more successful and took 4 times as many female bears per hunter than those not using dogs. However, the impact of hunting with dogs on the total harvest for a region depends on the proportion of hunters using dogs.

Timing of hunting seasons influences the total black bear harvest and the proportion of females in the harvest. During 1990-1999, later fall seasons were associated with lower total harvest and lower proportions of females in the harvest, compared to earlier fall seasons and spring seasons.

Environmental conditions can influence the effect of a hunt on harvest magnitude and composition. During 1993-1999, failures in oak production were associated with increases in hunter effort, hunter success, and the proportion of females in the kill.

CHAPTER 14

THE BLACK BEAR POPULATION MODEL

Our objective in this chapter is to develop and describe the bear population model as a tool for integrating harvest and biological information, and forming interpretations that are consistent with existing knowledge. This approach is intended to help managers to interpret harvest data in the context of bear population biology, make inferences about bear population size and status consistent with available harvest and biological information, and evaluate consequences of management options to bear populations. The model is designed to simulate population behaviors that are realistic for conditions in New Mexico.

CONCEPTUAL BACKGROUND

Information available to managers about black bears in New Mexico has traditionally been limited to data from hunter-killed bears. This study augments management information with biological data on New Mexico's black bear populations, improved understanding of the influence of annual variation in mast abundance, and estimates of potential bear density in different habitats. How can a manager use this diverse information to make inferences about the status of regional black bear populations and the potential consequences of harvest regulations? The population model is the tool for integrating harvest numbers, vital rates, and environmental relationships into a coherent whole.

Models of bear populations have been used for estimating population parameters, projecting population trends from vital rates, determining upper limits on sustainable mortality, and demonstrating various relationships between population and harvest composition. Treatment of biological detail and temporal variability has differed, depending on modeling objectives and information available.

Taylor et al. (1987) developed the ANURSUS model for estimating natality rates for polar bear populations from age specific litter size and family group observations. They emphasized the importance of accounting for the effect of whole litter loss on reproductive eligibility and litter intervals for animals with multi-year reproductive cycles.

Whether a population is increasing or decreasing, and why, are more important to management than population size (Eberhardt and Knight 1996). Assessment of population trends for Yellowstone grizzlies has been approached through comparison of female survival before and after sexual maturity, age of first reproduction, and reproductive rates, rather than through direct population size estimation (Eberhardt 1990, Eberhardt et al. 1994). These models use

detailed biological information, and infer trends from average rate estimates. For small populations, perturbations of age and sex structure influence dynamics for many years (Knight and Eberhardt 1985). Such perturbations can affect estimates of and projections from vital rates.

A simple model with detailed reproduction (average age of first reproduction, litter size, breeding interval) and constant mortality was described by Bunnell and Tait (1981). They related maximum sustainable mortality to reproductive characteristics for several documented populations of grizzly, polar, and black bears, and aided other insights into bear population dynamics.

Consequences of food related variation in natality, particularly synchronized or alternating reproductive schedules, were modeled by McLaughlin (1998). He imposed patterns of variable parturition on an individual based, stochastic simulation model with detailed reproductive biology and density dependent mortality, and found a substantial impact on sustainable mortality rates for females.

Population viability assessment models (e.g., Weigand et al. 1998) and other stochastic, individual based models (Knight and Eberhardt 1985) are useful for small or endangered populations where chance is a significant contributor to population variability and probability of extinction is a management concern.

Abundant, detailed biological information is not available to many bear managers, but almost all have harvest data. However, inferring population trend from harvest data alone is nearly impossible (Bunnell and Tait 1980, Garshelis 1991, Miller 1990). A stable age and sex composition in both the live population and the harvest can occur when the live population is stable, but also when it is increasing or declining (Miller 1990). A predominantly male harvest is possible from a predominantly female population (Bunnell and Tait 1980). The erroneous assumption of a constant harvest mortality rate can lead to misinterpretation of harvest data (Garshelis 1991). However, models can be used to demonstrate counterintuitive relationships between simulated populations and harvest data, warning managers of the possibility of drawing false conclusions from pelt data.

Modeling with constant rates can provide useful insights on the boundaries of possible bear population behavior. However, vital rates are variable in real populations, and the particular patterns of variation influence population structure for long time periods. Stochastic modeling provides implicit variation in vital rates over time, but the time pattern of the variation is not related to observed habitat conditions, cohort size, or harvest numbers. Selected general patterns of cohort variation have been examined. The consequences of hypothetical variation in survival over time to population age structure have been used to demonstrate problems in relating harvest data to population status. However, bear models have rarely dealt with the implications of specific

population histories. The perils of population assessment from harvest data alone are well documented. Modeling tools for integrating harvest data, biological information, and population history are needed.

METHODS

The bear population model was designed to simulate a black bear population through time, with biological realism, hunting, and environmental influences. Choices for population structure and for life history events accommodated population concerns, hunting patterns, and age of first reproduction for New Mexico. Input requirements were based on information anticipated from the field study for vital rates and bear densities, information routinely collected by NMDGF from hunters on effort and kills, and readily obtained environmental information important to bears. Outputs were chosen to track changes in population numbers and composition, as well as realized mortality rates and harvest predictions for comparison with observations. A set of functions with vital rates as arguments was developed to describe annual births, deaths, and age shifts. Additional functions related annual vital rate changes to environment (mast index, den entry timing) and hunting (effort and season timing). Functions for migration and population size constraints were added last.

Sets of vital rates from the study areas and regional pelt tag (hunter-kill) records were developed and stored with the model. A library of regional history simulations and teaching (hypothetical) model scenarios was developed.

Model software was programmed in APL (Array Processing Language, APL2000 APL+Win version 3.6) with a user interface in Windows Graphic User Interface (GUI) format. Installation is from CDDOM, programmed with Install Shield Express version 2.13. Automated output graphics are displayed using Microsoft Excel (version from Office 97 or later).

The model is implemented in a Windows Graphics User Interface (GUI) program, with a user shell to facilitate inputs, outputs, and scenario saves. Outputs are in both table and graphic formats. The model installation program is provided on CDROM with this report. The model CDROM also contains a library of scenarios, user manual, and documentation for the core model calculations.

The model user interface provides an assortment of aids to choosing input values, including stored characteristic rate sets for geographic regions of New Mexico, and hunt season and pelt tag (hunter-kill) report historic data sets.

RESULTS

Conceptual Model Structure

Overview. The bear population model (Appendix E) simulates a hunted bear population, tracking changes in numbers and sex-age composition over time based on births, deaths, and migrants (Figure 14-1). The initial population, characteristic vital rates, and annual variation in environment and hunting are inputs to the model. The core model equations are a calculation engine to change population numbers based on varying rates over time (Appendix F). Details of bear reproductive biology are incorporated into the model calculations. The model extrapolates population changes based on the conditions described by the full set of model inputs. Outputs are detailed population and harvest numbers and realized total mortality rates over time.

Vital rates are age and sex specific, and vary from year to year in response to environment and hunting. Vital rates are not explicit functions of density dependence or social structure. Migration of subadult males is optional and depends on threshold population sex proportions. Optional upper limits on total population and total adult females approximate density dependence at high population levels.

Population composition. The model's population age structure has separate age classes for each year from cub through 4 years, and an adult class containing ages 5 and above combined. Each age class also is separated by sex. Adult females are partitioned into groups with cubs, with yearlings, and with no offspring.

Scale. The modeled population should represent a large geographic area with a reasonably well-defined bear population, such as a mountain range. The model is not suitable for very small areas or small population subsets. Model runs typically simulate a population for 20 years or longer.

Annual variation. Mast availability index and den entry timing represent annual variation in environmental conditions. Hunting occurs in the fall, with annual variation in effort and season start dates. Fall mast index (poor, fair, or good) may be input for each year, or randomized based on input frequencies for each index level. Annual den entry is input as normal or late for each year. Hunt season dates may be loaded from historic data files; annual low, average, or high effort must be input for each year. Although the model is deterministic, it allows for unlimited patterns of variation over time.

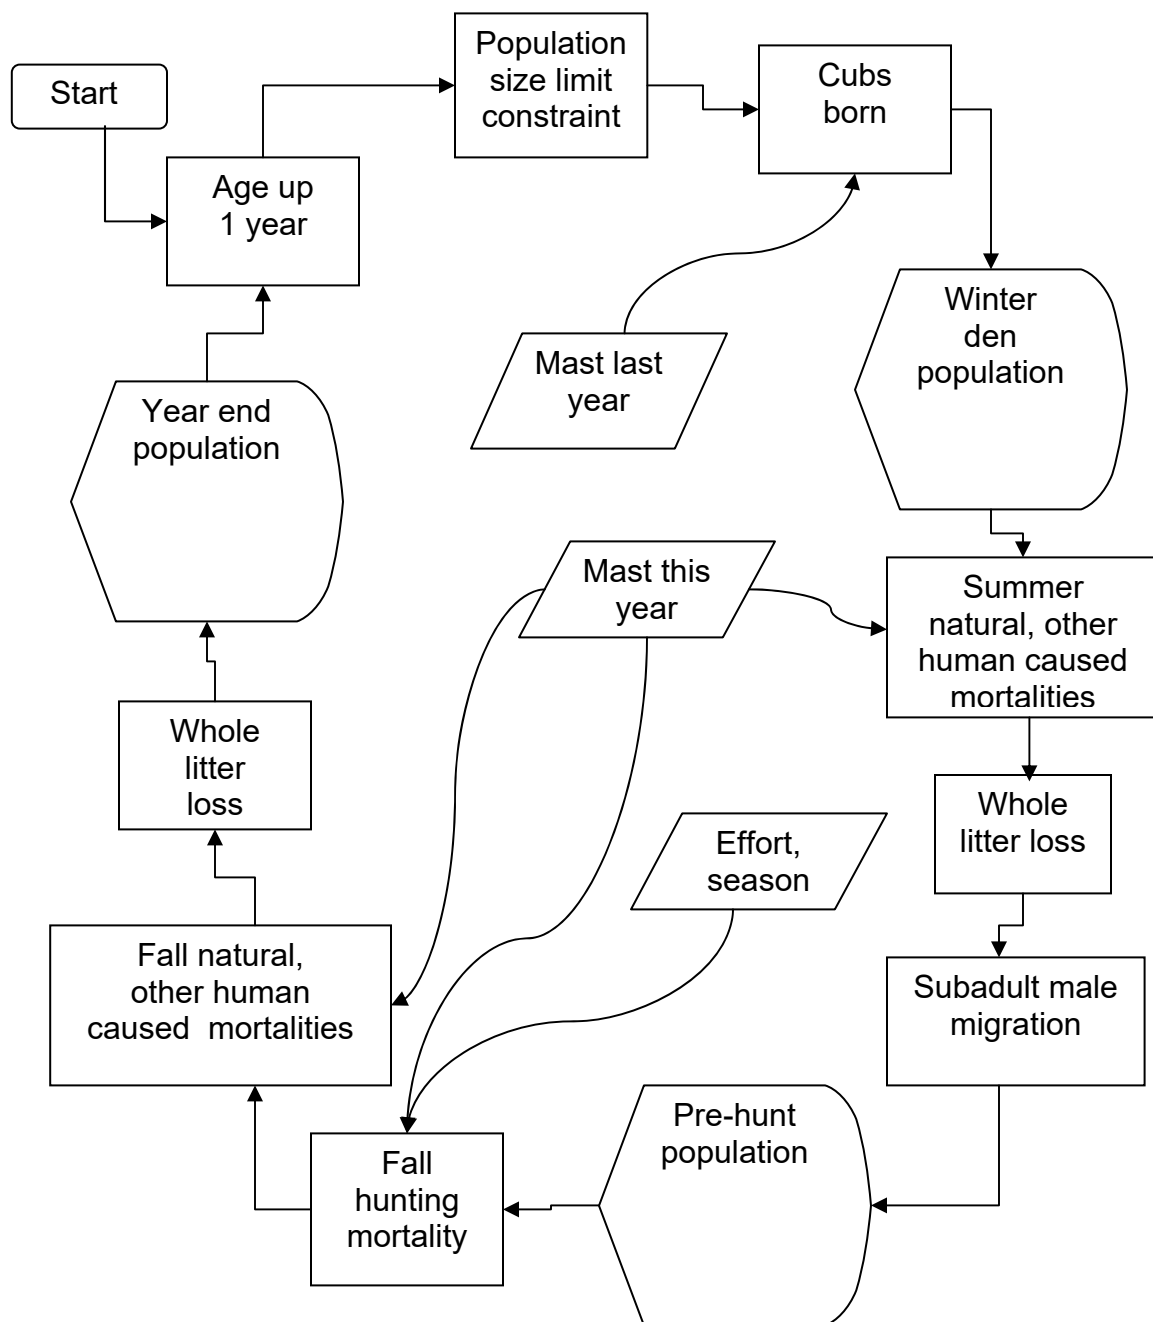

Figure 14-1. Schematic of sequence of events for a simulated year in the bear population model, New Mexico Black Bear Study, 1993-2000.

Natality. Parturition and cub survival rate inputs are step functions of poor, fair, and good mast availability and characteristic of the population being modeled. Fall mast each year determines cub survival rate for cubs born the previous winter and parturition rates for eligible adult females the following winter. Adult females with yearlings in dens do not give birth. Parturition rate is applied only to eligible adult females, defined as adult females without yearlings in dens. Cohort size variation and synchronized alternate year reproduction can be simulated. Calculated cub numbers are based on number of eligible mothers, parturition rate, and litter size frequency. Whole litter loss prior to hunting and prior to the following denning season is based on litter size frequency and cub survival. Whole litter loss in either time period classifies an adult female as eligible to give birth the next year, corresponding to the estimation of parturition rates for all adult females without yearlings in dens in this study.

Mortality. Long-term average mortality rate inputs characteristic of the population being modeled are age and sex specific, and partitioned into natural, hunting, and other human causes. Rates are additive. Hunting mortality varies as the characteristic rate is modified each year by hunt effort, season timing in relation to den entry, and mast conditions. Annual realized mortality rates, or characteristic rates modified by environmental factors, are an explicit output.

Hunting. The model can be run with hunt mortality rates as inputs, and hunter kills or pelt numbers as outputs. Alternatively it can be run with tagged pelt numbers as inputs, and the associated hunt mortality rates as outputs. The choice can be made separately for each year in the simulation. Forcing harvest numbers is useful for simulating unusual events such as the large 1994 harvest. Forcing harvest also makes explicit use of the NMDGF's long-term ongoing harvest pelt tag report data collection (see Chapter 13). Regional harvest data history files are stored with the model. Only fall hunts, the current NMDGF practice, have been implemented; a spring hunt could be added to a later version of the population model.

Scenarios. A scenario is the complete set of inputs for a model run. Scenarios may be saved and restored. Data interpretation using the model should be based on sets of scenarios, not on single runs. Sets of scenarios bracketing the range of uncertainty for inputs of interest or concern produce a set of outputs representing a plausible range of outcomes.

DISCUSSION

Limitations and Advantages of the Model

The New Mexico bear population model is deterministic. It is not suitable for assessing extinction probabilities or for modeling very small populations

where chance is a significant influence. A set of runs with varied inputs is necessary to achieve a range of plausible outcomes. The model is intended for simulation of viable, hunted populations, not endangered ones.

The model does not predict vital rates or environmental variation, although it allows variation in environment to modify realized rates over time. The influence of habitat quality can be expressed by choice of characteristic vital rates. Inputs are detailed, a disadvantage when biological information is sparse, but an advantage for simulating the particular conditions experienced by a real population. Annual mast index is an explicit input, allowing use of observations when available. Mast variation can also be randomized, based on frequencies characteristic of the geographic area being modeled.

The influence of bear social structure on population dynamics is not modeled explicitly. Migration of 3-year-old males in or out of the population can be included, activated by selected threshold population sex ratios. However, interpretation of the results of simulations allowing subadult male migrants should include the plausibility of an external population source for immigrants. An upper limit on adult females and on total bears can approximate density dependence and habitat carrying capacity. The model is sensitive to upper limits, so choices should be based on habitat types and potential densities where possible.

Reproductive biology is modeled in detail. Females with cubs and probability of whole litter loss are tracked for reproductive eligibility and for hunting vulnerability. There are not separate age classes for adult females and parturition rates are average for all adult females, not age specific, because age specific reproductive rate data will not be generally available for New Mexico populations. Age at first reproduction is effectively 5 years, the approximate average for New Mexico. However, reduced parturition in mast failure years is equivalent to older age of first reproduction under poor environmental conditions. Parturition rate is not affected by adult sex ratios, since depressed reproduction due to scarce males is not a problem in New Mexico. However, no cubs are produced if there are no adult males in the simulated population.

Hunt season timing or closure and hunting effort are inputs, allowing management options to be explicit inputs for simulations. The current version allows hunting only in the fall, the current practice in New Mexico. The addition of a spring hunt option would expand the utility of the model.

The New Mexico bear model is designed to facilitate a synthesis of harvest data, population biology, and information on environmental variability. Resulting inferences about bear populations are consistent with all available information. The model cannot provide certainty, but it can rule out nonsense.

When good information is available on annual mast availability, harvest numbers with sex and age, and an upper limit or carrying capacity number of adult females for a population, in conjunction with the vital rate estimates from this study, model results can be of considerable use to managers. Scenarios with population constraints are more sensitive to the combination of harvest numbers, mast failure frequency, and carrying capacity than to rate estimates. Mast, harvest, and carrying capacity can indicate potential over harvest; vital rates can indicate potential for recovery.

Some Strategic Uses of the Model

Real population status. Use of the model to assess population status requires criteria for recognizing a plausible simulation. The criteria will combine best available information for rates and environmental inputs, and information on historic harvests to compare with outputs. To establish criteria for an acceptable simulation, (1) determine reasonable harvest and total mortality rates for the region and time period, (2) use measured mast indices, or any other indicators of mast availability for each year, or use a reasonable frequency of mast failure and randomize mast index over time, (3) note hunt season start dates and identify years with unusually low or high hunter effort, (4) from pelt records, calculate the average numbers of harvests by sex for the time period, and identify years of unusually low or high harvests, and (5) find indications of cohort size variation from harvest data records or independent observations. Run the model using the most plausible rate, environment, and hunt condition inputs. If necessary, make additional runs, varying the initial population numbers until the predicted average female harvest agrees with the observed average, to ensure a plausible initial population size. Then evaluate other outputs against criteria for a plausible simulation. Check predicted variations in cohort size and total harvest for agreement with observed patterns over time. If harvest numbers were forced (inputs) for some years, check the realized hunting and total mortality rates for those years for plausibility. A simulation with plausible inputs and with outputs consistent with observation provides a plausible assessment of population size and trend, consistent with available information.

Hypothetical population behavior. To investigate bear population behavior in general, use an arbitrary initial population with a reasonable age and sex composition, and vary characteristic rates or environmental conditions while leaving the initial population unchanged. Compare patterns in outputs over time, rather than numbers, to see how populations and harvest size and composition respond to different conditions. For example, change mast failure frequency to see the impact on population growth and harvest composition. Increase characteristic harvest and total mortality rates to find levels of over-harvest associated with population reproductive rates, and observe how harvest number and composition predictions change at the same time. Or simulate different

hunting regimes over time for comparison, and include environmental variation for realism.

Examples from literature. The model can also be used to reproduce cautionary examples derived from technical literature concerning the problems of relating population status to harvest composition. An example is the counterintuitive finding that a predominantly female population is consistent with a predominantly male harvest, or that population and harvest age and sex composition can remain stable while population size is increasing, stable, or decreasing. The model user can thus be educated about the difficulties of interpreting harvest data, and avoid unwarranted deductions.

Reasonable Input Values

Characteristic vital rates. Estimating vital rates with minimal uncertainty is difficult for bear populations. Allowing rates to vary with environment and hunting is more important to model interpretations than getting average rates exactly right. The field study has produced reproductive and mortality rate estimates for New Mexico, although measured hunting mortalities are suspected to be low in some cases, providing the basis for reasonable input values for the population model (Tables 14-1 and 14-2).

Table 14-1. Black bear population model inputs for characteristic natality rates based on field study observations, New Mexico Black Bear Study 1993-2000.

Litter size frequency			Mast index frequency			
<u>No. cubs</u>	<u>NSA</u>	<u>SSA</u>	<u>Model label</u>	<u>Mast classification</u>	<u>NSA</u>	<u>SSA</u>
single	14	13	Poor	Fail	1	4
twins	43	24	Fair	Poor	4	2
triplets	4	1	Good	Medium or better	3	2

Mast index		Parturition rate		Cub survival	
<u>Model label</u>	<u>Mast classification</u>	<u>NSA</u>	<u>SSA</u>	<u>NSA</u>	<u>SSA</u>
Poor	Fail	0	0.39	0.50	0.43
Fair	Poor	0.71	0.67	0.50	0.85
Good	Medium or better	0.78	0.77	0.50	0.85

Choices for characteristic rate inputs have significant impact on model outputs, reflecting realistic uncertainty about bear population dynamics. Sets of simulations with different characteristic rates are needed to assess the impact of uncertainty on population inferences, and to bracket a range of plausible inferences.

Table 14-2. Observations and reasonable ranges for characteristic mortality rate inputs to the population model for female (F) and male (M) black bears on the Northern Study Area (NSA) and Southern Study Area (SSA), New Mexico Black Bear Study 1993-2000.

Population category	Hunt mortality rate			Total mortality rate		
	NSA	SSA	Reasonable range	NSA	SSA	Reasonable range
F Yearling	0	0	0.02 - 0.03	0.25	0.03	0.10 - 0.30
F Subadult	0.05	0.04	0.04 - 0.08	0.06 - 0.14	0.09 - 0.11	0.05 - 0.15
F Adult	0.04	0.07	0.04 - 0.08	0.07 - 0.08	0.10	0.08 - 0.20
M Yearling	0	0	0.02 - 0.05	0.10 - 0.13	0.24	0.10 - 0.30
M Subadult	0	0	0.07 - 0.10	0.05	0 - 0.03	0.08 - 0.25
M Adult	0.02	0.07	0.07 - 0.10	0.08	0.09 - 0.18	0.10 - 0.25

Choices for characteristic rates can be used to describe conditions for a particular population. Natality rates can be adjusted to represent habitat quality differences. Mortality rates can be increased for areas with many roads or other disturbances.

The model allows for characteristic natality rates associated with 3 levels of mast abundance. Study results indicate that only 2 levels, failure or not, are significant (see Chapters 5 and 6). To reconcile the model structure and the study findings, use the model category of poor mast abundance for failure conditions, and assign the same rates to the fair and good model categories for non-failure conditions, taking care to indicate the correct frequencies for the failure and non-failure categories. Alternatively, assign a 0 frequency to the good mast category in the model, and use the poor and fair categories to represent failure and non-failure conditions.

Initial population numbers. The model addresses changes in populations over time. Each simulation or model run requires a starting population as an input. When vital rate and environmental inputs are reasonable, but model outputs of pelt numbers or realized total mortalities are not consistent with observations, then the simulated population is not plausible, and the initial population input should be changed.

Where possible, use GIS habitat extent, quality and associated bear home range size to estimate total male and female numbers, and use those as inputs. Partition the totals by age using default proportions or use extrapolated study area population structure as a guide.

If habitat based estimates are not available, consider a manager's informed estimate of total bears in the region as a starting point. Using the model will provide a check on the plausibility of such estimates.

When there is no other basis for selecting an initial population size, the model can be used to generate ballpark initial populations from harvest data, with the following steps: (1) Select and load a set of characteristic vital rates based on geography from rates stored with the model. (2) Set mast values to average for all years, so that reproductive rates will be steady at average values. (3) Start with an arbitrary total of 1000 bears, and run the model for 20 years. (4) Use the final population from that simulation, which will have age and sex proportions consistent with the vital rates, as the initial population for the next run. This step eliminates the influence of unstable population age structure on average harvest. (5) Run the model again, and compare the average total pelts and female pelts to pelt tag observations. (6) Adjust the initial total numbers up or down until predicted average pelts are similar to observed average harvest. Then use that initial population for simulations with variations in environment and hunting.

One use of the model is testing a range of population sizes for plausibility in light of past harvest history and mast availability by repeated runs varying only initial population totals. Take care to avoid other input constraints that may invalidate the population size interpretation.

Application outside of New Mexico. The model can be applied to black bear populations in other locations by suitable choices of characteristic vital rates, litter size frequencies, and mast frequencies and mast step function values. The input details allow considerable opportunity for simulating particular conditions. In this version, simulated hunting is limited to a single fall season.

Modeling study population viability

The model was used to investigate the implications of observed natality and total mortality rates from both study areas. Natality rates from Table 14-1 were used as model inputs. Calculation of long term averages weighted by frequencies shows the NSA had an average parturition rate for eligible adult females of 0.65, and average litter size of 1.84. The SSA had lower average reproductive rates, with 0.51 for parturition rate and 1.68 average litter size. Observed total mortality rates for the study areas from Table 14-2 were entered as characteristic natural mortality, with other human and hunting mortality rates set to zero, for correct total realized mortality. Where the total mortality estimate was a range (excluding or including probable deaths), the mid point of the range was used for the input value.

Initial population age and sex composition were based on history scenarios previously developed for the surrounding mountain ranges, but total numbers were rounded to the nearest 1000 for simplicity. This analysis considers proportional population changes rather than absolute numbers, so the initial total numbers used do not affect the interpretations.

Some simulations were made with mast set to average for all years, to produce constant average natality rates. Additional runs were made with randomized mast values, using the frequencies characteristic of the study areas, so that cub production varied. Cub survival varied with mast, but total mortality rates for older bears were constant at input rates. For each study area, 1 run used mast index set to observed levels for 1993-2000. Since observed mortalities on the study areas appear unrealistic for female yearlings on both areas and subadult males on the SSA, simulations were also run with total mortalities set to the minimum, middle, and maximum of the reasonable ranges for each population category. Changes in adult female numbers from beginning to end of the simulations varied from 199% increase to 84% decrease, depending on the combination of mast conditions and mortality rates used (Table 14-3).

The interpretation of simulation results will focus on adult females, because their numbers determine the reproductive potential of the populations. Our observations of subadult male total mortality are unrealistically low, skewing the simulated male numbers and the simulated population sex composition.

These simulations are not realistic, because constant rates over time are not realistic, but they reveal the population trends implied by the observed average rates. Both populations have a built in tendency to increase, based on observed rates. The unhunted NSA has lower mortality for subadult and adult females, and higher potential reproduction because of its low frequency of mast failures, and so has potential to increase faster than the SSA.

The potential for increase is overestimated if total mortality for females has been underestimated. For both study areas, the average annual female total mortality is 10%. Model simulations with the same total mortality rate for all female age classes and average observed natality rates show that the NSA population would begin to decrease with average total female mortality above 12.5%, and the SSA population would begin to decrease with average total female mortality of 11.5%, well within the range of uncertainty for the observed rates.

Table 14-3. Percent changes in adult female numbers from bear population model runs using study area vital rates and mast observations for the Northern Study Area (NSA) and Southern Study Area (SSA), Black Bear Study in New Mexico 1993-2000.

Time frame	Constant average mortality rate	Mast	NSA female population change	SSA female population change
20 years	Study area observations	Constant at average	+117%	+49%
20 years	Study area observations	Randomized	+39 -128%	+40 - 86%
1992-2000	Study area observations	Study observations	+23%	+14%
20 years	Minimum of reasonable range	Constant at average	+199%	+129%
20 years	Middle of reasonable range	Constant at average	-16%	-34%
20 years	Maximum of reasonable range	Constant at average	-79%	-84%

The simulations with observed mast abundance indicate that both study populations have increased during the study. There were no marked bears killed from the SSA population during 1994, the year of record harvests for both sexes in the surrounding Gila region, but marking began only in 1993. If unmarked females resident on the SSA were killed in 1994, the study population may not have increased.

The pattern of mast abundance over time strongly affects simulated population trends, with all other inputs left unchanged. Routine observation of mast abundance would greatly enhance utility of the model and assessment of population status.

Modeling Pelt Tag Data Histories

In workshops held in 1998 and 1999, NMDGF area managers used the population model to assess black bear populations in 4 mountain range regions comprising most of the state's bear habitat (Table 14-4). Simulations used vital rates and mast observations from the study areas for the Gila and Sangre de Cristo complexes, and similar rates for the San Juan complex and Sacramento region with adjustments based on area managers' knowledge of local conditions. Simulations were run for 1981-1998. Outputs were evaluated for plausibility based on comparisons with observed average pelts tagged by sex for 1989-1998, timing of peak harvests, and proportions of subadults. Scenarios with reasonable matches to observed patterns provide interpretations of bear population status that are consistent with both pelt tag observations and field study findings.

Table 14-4. Regional black bear population status interpretations based on population model simulations and harvest observations in New Mexico, 1989-1998.

Region	Rough population estimate	Trend	Observed average no. bear kills 1989-1998		Model average no. bear kills 1989-1998		Pelt tag numbers forced	Scenario name
			F	M	F	M		
Sangre de Cristo complex	1500	Slow increase	40	67	41	56	none	SANG99D
San Juan complex	1000 hunted + 700 unhunted?	Slow increase	26	44	25	35	none	SNJN99C
Gila complex	1000	Stable	35	58	37	43	1989, 1994	GILA99B
Sacramento region	1000	Increasing	24	33	23	35	1994, 1995	SE99B

Sangre de Cristo complex. Scenarios were based on NSA rates, but with higher adult hunting and total mortality rates, because most of the region is hunted (although the study area was not). A scenario with constant hunt effort and observed mast pattern for the study years produced a slowly increasing population with reasonable harvest patterns but low average numbers, and a peak in kills for 1994. Initial population was increased to raise average pelt tag numbers, and hunt effort was specified as low for 1992 and high for 1995,

consistent with card survey results. The final scenario showed a gradual increase in the live population total. Scenario average pelt numbers for males were lower than observed, suggesting that the hunt component of male mortality may have been underestimated.

San Juan complex. Scenarios were based on NSA rates, but with higher adult hunting and total mortality rates, because part of the region is hunted (although the study area was not). . Mast index inputs were based on knowledge of local conditions, not northern study area observations. Runs with slightly increasing population and a reasonable match for observed female pelt tag reports had lower male pelt tag numbers than observed. The large areas of this region protected from hunting may be a source of some of the males killed by hunters.

Gila complex. Southern study area vital rates were used, except that a higher subadult female hunt mortality (same as for adult females) was needed to match the observed proportions for subadults of females in pelt tag reports. High harvest numbers for 1989 and 1994 were forced because simulations did not produce the observed peaks. For 1994, with the harvest forced to match the high observed pelt tag report numbers, realized total mortality for the year was 22% for females, 35% for adult males, and 42% for subadult males; area managers interpreted the high mortality values as reasonable for the unusually harsh conditions of 1994. In a scenario that produced a good match to observed pelt tag numbers and proportions for females, the 1994 harvest reduced the pool of adult females in the model population, so that the population fluctuated around initial 1981 population numbers without much change over time (Figure 14-2). Scenarios that matched observed female pelts predicted too few male pelts. The discrepancy could be reduced by assuming substantial immigration of subadult males from Arizona, or by shifting all subadult male mortality from other causes into hunting, or by a higher total population with much lower female hunting mortality.

Sacramento region. A population scenario with fast turnover, both natality and mortality near the high end of reasonable ranges, is consistent with the observed high proportions of subadults in pelt tag reports. With the large 1994 and 1995 pelt tag observations forced, a scenario with a slowly increasing population predicts harvests that agree with both observed numbers and proportions. There is no likely source of immigrant subadult males for this population, and the scenario does not need 1 because these mountain ranges are isolated from sources of immigrants.

Total harvest

Simulated population

Figure 14-2. Black bear population and harvest numbers simulation

Statewide. The steady decrease in statewide hunter-killed bears from 625 in 1994 to 148 in 1998 raises concern about over-harvest. That pattern was exaggerated by the large harvest in the Gila complex in 1994; although present, the pattern is much less marked in other regions. Harvests increased again in 1999 and 2000. License sales decreased steadily from 1995 through 1998, and the 1998 season was 6 weeks later than previous years. Model population simulations with field study rates indicate that the peak harvests likely resulted from mast failure combined with an abundance of available subadults born in the early 1990s, and subsequent decreases were likely related to decreasing hunter numbers rather than to a rapid drop in bear populations.

Pelt tag reports show a higher proportion of males than do simulations based on vital rates observed during field study. The difference may result from difficulty in documenting male bear mortality rates, or from inclusion of immigrant subadult males in harvest reports, or both. Focusing on the female segment of the population for interpreting population changes avoids the problem.

Model Application to Management

Simulations used for the following model application discussions are included with the population model software in the scenario library (Table 14-5).

How fast can a population change? In simulations with all mortality rates at the high end of reasonable ranges based on study, model populations disappear in 2 or 3 decades. The persistence of bears is evidence against the plausibility of the long-term maximum mortality rate simulations. Populations with average natality like the SSA would decrease by 61 – 79% in 10 years and by 85 – 96% in 20 years with constant annual mortality rates of 20 – 25% for all population categories. Populations with average natality like the NSA would decrease by 56 – 75% in 10 years and by 80 – 94% in 20 years.

Minimum mortality simulations, while not realistic, identify an upper limit on bear population growth rates in New Mexico. Unless limited by habitat capacity, southern populations might double in 20 years, and northern populations might triple, if mortality were minimal and the pattern of mast availability remained normal. Since most New Mexico populations are hunted, the fastest population increase possible with persistent low mortality would be doubling in 20 years. With occasional years of greater mortality, population increases are reasonably expected to be slower.

Average statewide hunter kills for 1994 and 1995 were double the average for 1991-1993. This increase must be interpreted as increased hunting mortality rate, and not as a proportional increase in total population with unchanged harvest mortality, because the population could not have doubled during that

time frame. Similarly, the decrease in total pelts tagged from 625 in 1994 to 148 in 1998 cannot be interpreted as evidence of a 75% reduction in population in 5 years, because such a rapid drop would be highly unlikely. Instead, other factors should be considered along with the possibility of a less rapid population decrease.

Table 14-5. Scenarios used for the black bear population model application discussion and stored in the scenario library, Black Bear Study in New Mexico, 1993-2000.

Scenario library name	Description of scenario	Interpretation section
NSAOBS01	Constant mast, NSA characteristic vital rates	Study population viability
SSAOBS01	Constant mast, SSA characteristic vital rates	Study population viability
CUBVAR1	Population varying slightly around a stable total	Synchronous reproduction
OVER0	Baseline stable population with annual variations	Characteristics of over harvest
OVER1x	Persistent mast and reproductive failure	Characteristics of over harvest
OVER2x	Increased hunt mortality	Characteristics of over harvest
OVER3x	Increased nonhunt mortality	Characteristics of over harvest
SANG99D	Sangre de Cristo pelts, NSA rates	Pelt tag histories
SNJN99C	San Juan pelts, modified NSA rates	Pelt tag histories
GILA99B	Gila pelts, SSA rates	Pelt tag histories
SE99B	Southeast pelts, modified SSA rates	Pelt tag histories

Cohort variation, synchronized reproduction, and pelt age composition.

The baseline scenario simulates a hypothetical population varying slightly around a stable total for 20 years. Mast index and the associated natality and cub survival rates vary annually. The population age composition changes over time as variable size cohorts age. Hunt effort is held constant so that realized total mortality rates for yearling, subadult, and adult bears remain constant. Predicted hunter kills or pelt tag numbers vary slightly with population size and composition over time. The proportions of subadults in the pelts vary from 35 to 53%, with several large drops over a few years; however, total population size is essentially stable (Figure 14-3). This simulation demonstrates that shifting proportions of subadults in hunter-killed bears may indicate, and lag, cohort variations, but do not necessarily indicate population size change.

Figure 14-3. Simulation of black bear cohort size variation and its influence on harvest age composition in a 20 year stable population simulation for data applicable to black bears in New Mexico.

Synchronized reproduction can be simulated. Constant rate scenarios provide a basis for examining synchrony, by following the impact of a single mast failure over time. One year of mast failure in a simulation with NSA natality rates and otherwise all fair mast produces almost no cubs in the year following the mast failure, a very large cohort in the second year, and a smaller than normal cohort the third year. Variations continue for several more years, but with differences too small to be noticeable. A similar pattern occurs with SSA natality rates, except that the initial mast failure produces 2 cohorts about half average size since the mast failure reduces survival for cubs already born as well as parturition for the next year's cohort. A single mast failure affects cohort size for 3 or 4 years. Any single year's observation of population composition may misrepresent the longer time scale pattern. Averages over 2 to 4 years are useful for examining patterns over long time periods.

Characteristics of over-harvest. The model was used to investigate potential indicators of over-harvest and declining populations. A 20 year simulation of a hypothetical population fluctuating around a steady mean, with annual variations in mast index and 2 years each of high and low hunt effort, was used as a baseline. Declining populations were simulated by mast and reproductive failure, increased non-hunt mortality, and increased hunt mortality. For each cause of decline, runs were made with hunt mortality determining pelt numbers and with pelt numbers specified resulting in increasing hunt mortalities in the second decade. The hypothetical scenarios used for this discussion are stored in the model scenario library.

In the baseline simulation, pelt numbers fluctuated from year to year with cohort and hunt effort variations, but remained stable on average. The proportion of females varied in the range of 46-51%, and the proportion of subadults varied in the range of 34 – 44%, with no trends over time.

In all of the declining population simulations without forced pelt tag numbers, simulated harvest numbers fluctuated, but relative peaks decreased and averages clearly dropped over time. In the stable population simulation, harvest numbers were steady on average. In other simulations with increasing populations, pelt numbers increased on average. Trends in harvest numbers should indicate population trends if hunting effort remains reasonably constant and if harvest numbers are related to bear numbers, that is if hunting mortality rate has some reasonable upper limit. The problem with depending on pelt tagging report numbers as a population indicator lies in the assumptions. In New Mexico, changes in hunt season dates and substantial variation in numbers of hunters produce variations in hunt effort, so that patterns in pelt numbers must be interpreted in conjunction with patterns in hunter numbers and seasons. A persistent decrease in total pelts over 4 years or more without a related decrease

in hunting effort should be investigated as a potential indication of a population decline.

Simulations with forced pelt tag numbers can represent cases of harvest numbers not related to bear numbers, so that hunt mortality increases until hunters take all bears. If hunters can kill the same numbers of bears at high and low bear population levels, then pelt number patterns are not a reliable indicator of live population trends.

The age and sex composition of pelts from populations declining due to increased mortality rates did not differ noticeably from the baseline stable population simulation. In the simulation with persistent reproductive failure, the proportion of subadults in pelts decreased by half in 6 years, and then remained low but stable. In the reproductive failure case, independent information on persistent mast failures would alert managers to a probable population decline before pelt age changes could become obvious. Changes in pelt sex and age composition are not useful indicators of population size trends. Age and sex of pelts does provide useful information on relative cohort sizes and impacts on the pool of reproductive females, however.

In the simulations of populations declining from increased hunt or nonhunt mortality rates, the population declines could be stopped or reversed by reducing hunt mortality. In the simulation of population decline from reproductive failure, the rate of the decline was slowed with reduced hunt mortality.

Declining populations are hard to recognize from pelt tag data alone. Decreased pelt numbers without decreased hunt effort would indicate a declining live population, but would take perhaps a decade to become apparent. The bear model provides a context for interpreting pelt numbers; interpretations are considerably strengthened by the incorporation of other information such as mast observations, hunter numbers, and season timing.

Focus on female harvests. Initial experiments with the model are likely to produce frustration with the difficulty of forming definitive conclusions in the face of uncertainty about vital rates. Further experience with a variety of simulations will indicate that the pool of reproductive females is critical to population trends, an outcome that is not surprising. In New Mexico there is good information on harvest numbers. Even though female mortality rates are not known with certainty, unusually high female harvest numbers (well above averages from other years) can be recognized from pelt data, and imply unusually high female mortality for the year. In New Mexico there is a well-documented relationship between mast crop success or failure and reproductive success or failure (see Chapter 6). Continuing observations of fall mast will provide a good indication of annual variation in reproduction, and the associated variability in cohort size should be detectable from pelt ages. The model provides the capability of

simulating the population consequences of the real pattern of female harvest and reproduction over several years, key to assessing the potential for over-harvest. High female harvest numbers combined with poor reproduction need management attention.

MANAGEMENT IMPLICATIONS

The bear population model is a tool for integrating harvest and biological information, and forming interpretations that are consistent with existing knowledge. It helps managers to:

- Interpret harvest data in the context of bear population biology, including reproductive patterns and the influence of environmental conditions on vital rates, such as parturition and survival
- Make inferences about bear population size and status that are plausible and consistent with available harvest and biological information
- Evaluate the consequences of management options to bear populations

“Knowledge in, knowledge out” is the philosophy of bear model use. Inputs are the characteristics of the particular population to be modeled and the year-to-year changes in the conditions that affect that population. Outputs are predicted year-to-year changes in numbers and in age and sex composition of the live population and of hunter-killed bears. Model calculations link the outputs to the inputs based on knowledge of bear population dynamics. Model predictions are consistent with the inputs. Greater confidence in inputs means greater confidence that simulated population behavior is realistic.

The model simulates population behaviors that are realistic for conditions in New Mexico. There will always be considerable uncertainty in information about black bears. Because of this uncertainty, managers will not be able to use the population model for simple predictions of legal kills or population trends. The model will be useful for gaining insight about how bear populations can behave, and for discriminating between reasonable and unreasonable explanations of observed harvest trends.

The New Mexico bear model can incorporate variation in vital rates over time based on real population histories, through annual mast observations for natality variation, and annual harvest numbers for mortality variation. The consequent perturbations in live population structure and harvest composition can then be simulated and taken into account for population status interpretation.

The black bear population model can be a useful tool for understanding bear population dynamics, and educating the intuition of managers. Sufficient practice with the model is essential to appropriate interpretation.

Experimentation with the impacts of small changes in different inputs, or sensitivity analysis, will provide insight into the relative importance of different kinds of input information, allowing effort to focus on the most important variables.

When good input information is available, the black bear population model can be a useful tool for assessing population status. Continuing collection of hunt effort information through the hunter card survey and information on the number, sex, age, and location of hunter-killed bears through mandatory pelt tagging reports will be useful. Routine observation of fall mast abundance will be useful. Attention to habitat suitability, using GIS tools, will be useful.

Black bear population status appears to vary among mountain regions in New Mexico. Hunting regulations that vary among regions make sense from a population biology perspective.

Focusing the interpretation on bear population status on the female segment is useful, because the pool of adult females is critical to population maintenance. Annual variation in male harvest numbers is harder to interpret because subadult males may be migrants.

Be cautious in interpreting bear model predictions for conditions outside the range of experience from the bear study, including poorer habitats, different hunt regimes, and other climate conditions.

CHAPTER 15

MANAGEMENT TOOLS AND APPLICATIONS

It is vital that readers of this report and its appendices recognize that they are a tool for future management investigation and decision-making. Using the study results, the population and habitat models, and data collected annually by NMDGF, managers can explore the results and consequences of many management options. This product does not provide answers to all management questions; it provides the means to answer questions when used with reliable and up-to-date information.

EXISTING TOOLS

Hunter-Kill Data Records

Since 1978, the NMDGF has collected annual records of harvested bears through a mandatory tagging and reporting program. Beginning in 1985, utility of these data was improved with the requirement of proof of sex and collection of a premolar tooth for age determination with the cementum annuli method. This data set, known as the pelt tag records, also includes information on date, location, and method of kill.

Hunter Survey

Since 1989, the NMDGF also has conducted mail-in surveys of all buyers of bear hunting licenses to obtain data on hunter effort and methods to be used in conjunction with harvest records. These records, known as the card survey data, are collected and analyzed by the NMDGF Division of Wildlife.

NEW TOOLS

Bear Population Model

An important product of this study is a black bear population model that directly incorporates reproductive and survival rates observed during 8 years of field study, along with harvest data routinely collected by the New Mexico Department of Game and Fish. Utility of the model depends on continued input of data in the form of (1) annual hunter-kill (pelt tag) records and (2) annual observations of regional mast production.

Habitat Model

Another important product of this study is a model of predicted suitable habitat for black bears in New Mexico. This model is a relatively simple predictive algorithm that incorporates land cover classes (habitat types), land

cover class suitability for bears, mast production potential, and distance of isolated habitat tracts from primary habitat types. The model allows for examination of bear habitat with respect to other landscape features such as roads, distribution of hunter-killed bears, proximity to human population, and other factors that a resource manager may choose to evaluate. The model is designed to incorporate and integrate with new ecological and socioeconomic information as it becomes available.

Annual Mast Survey

The mast production survey implemented during this project is a procedure conducted by NMDGF personnel using categorical criteria to distinguish annual variation in mast production. Study results indicate that documenting annual mast production, particularly occurrence and frequency of mast failures, will be an effective tool for predicting future black bear reproductive success. In addition, knowledge of mast failure may aid in interpreting harvest data, because mast failure appeared to influence amount and composition of hunter harvests.

Research Report and Data sets

The Final Report and associated data sets (on CDs) provide extensive archiving of bear project data and interpretation of that information. Some of this information is supplemental to specific uses in the bear population model and habitat model. The report materials in total are a foundation for asking additional questions about managing black bears in New Mexico and describe uses of all of the tools mentioned here.

UNDERSTANDING THE TOOLS

Hunter-Kill Data

Hunter kill data provide information only from successful hunters. Continued collection of pelt tag report data is essential for estimating population trends using the bear population model. Analyses indicate ages of hunter-killed bears, estimated using the cementum annuli method, are sufficiently accurate to support interpretation of pelt tag data. Use of the bear population model requires age-specific data on bears aged 1-4 years, and distinguishing subadult from adult bears killed by hunters. Our analysis indicated the currently used age determination technique is most accurate and consistent for young bears. Procedural improvements, such as minimizing breakage and extracting the correct tooth, also will increase accuracy.

Analysis of pelt tag records from marked study bears indicated as many as 7% of hunter-killed bears reported to NMDGF are missing from finalized pelt tag data. Improvement in the flow of data from field personnel through area

offices to the Santa Fe office is necessary to ensure the most accurate data possible. Also, it is essential that UTM coordinates for locations of bear kills recorded on the pelt tag record be accurate and consistent with the GMU to maximize abilities to plot bear kill data with respect to habitat model output.

Hunter Survey

The hunter card survey collects information from unsuccessful as well as successful hunters, allowing estimation of effort and success rates. Continued collection of mail survey data is essential for knowledge of the geographic distribution of hunting effort, not available from statewide license sales or pelt tag records. Archiving raw survey response data will facilitate analysis beyond the routinely reported annual projections.

Projections of total hunter effort and harvest from card survey responses depend on total statewide license sales numbers. Because the state fiscal year is different from the regulation year, and license sales records are maintained for fiscal use, careful attention to appropriate total license numbers is important to card survey projections.

Surveys are mailed to all license holders with usable mailing addresses. Archiving mailing lists and noting undeliverable returns would improve knowledge of response rates, allow comparison of response rates by region, and facilitate follow up surveys of nonrespondents to assess bias.

Annual Mast Survey

Results of simplified surveys conducted by NMDGF officers were highly correlated with more intensive survey results, indicating quantified subjective criteria are adequate to distinguish variation in mast production. Most officers found the criteria were reasonably easy to use and could be completed during routine duties. In the future, an effort to establish general survey routes, revisited each year, may reduce unnecessary variability and ensure quality data.

Bear Population Model

The bear population model is a tool for (1) interpreting past or present conditions using real time series observations of harvest and mast, and (2) investigating demographic outcomes from hypothetical information based on realistic biological conditions and management actions. Model input variables are reproductive rates, survival rates; and mast production; outputs are predicted population composition and harvest composition. The inputs appear to be simple, but the user must be educated to the influences of factors such as hunt timing, methods, and regional differences in productivity and mortality. Information in the Final Report and interpretations from GIS habitat modeling are important resources for judging inputs for the bear population model.

Reliable information is essential for using the bear population model and interpreting its output. Continuing collection of hunt effort information through the hunter card survey and information on the number, sex, age, and location of hunter-killed bears through mandatory pelt tagging reports will be important for future management. Continued mast survey data are also essential inputs for the bear population model, because vital rates are deterministic functions of mast index in the model.

Information from this study indicated mean age of females at birth of first cubs was 5.7 years for study bears, and only 9% of 4-year-old bears produced first litters. Use of the population model assumes the adult segment of the bear population in New Mexico is bears ≥ 5 years old.

Sufficient practice with the model is essential to appropriate interpretation. Sensitivity analysis, or experimentation with the impacts of small changes in different inputs, will provide insight into the relative importance of different kinds of input information, allowing efforts to focus on the most important variables. Focusing interpretation of bear population status on the female segment is useful because the pool of adult females is critical to population maintenance. Annual variation in male harvest numbers is harder to interpret because subadult males may be migrants.

Caution is necessary in interpreting bear model predictions for conditions outside the range of experience from the bear study, including poorer habitats, different hunt regimes, and other climate conditions.

Habitat Model

At present, restrictions on availability of comprehensive, detailed, statewide information layers limit detailed analysis of habitat quality and potential effects of humans on bear survival. However, the model was constructed so that future, more resolved information can be easily incorporated to update model predictions. Such new data integration also applies to analytical uses of the habitat model to assess proximity to human-populated areas and other evidence of prospective human interaction with bears (e.g., traffic, recreation). The habitat model also may be useful in developing or verifying inputs to the bear population model, especially upper limits for modeled populations.

APPLYING THE TOOLS

Population Monitoring and Interpreting Hunter-Kill Data

Use of the bear population model, with the inputs described above, will (1) allow for interpretation of recent demographic trends in New Mexico bear populations, (2) provide a timely indication of potential overharvest, and (3)

provide predictive scenarios useful for selecting from several management options.

Although status and trends in black bear populations cannot be detected from harvest data alone, patterns in harvest data may flag areas of concern to managers. For example, missing cohorts and associated reduction in proportions of subadults in the harvest over several years may suggest poor reproduction.

Model vital rates are deterministic functions of mast index, which can be randomized with realistic frequencies, or matched to observations. Series of scenarios with different mast patterns or characteristic vital rates can be set up easily and run in a short time by NMDGF wildlife managers and researchers investigating further and future questions about bear population management. Outputs of interest must be recorded and organized for comparison; the model does not compare results of differing scenarios automatically.

Among adult and subadult bears, most mortality was human-caused. In addition to hunting, illegal kills and depredation kills were significant sources of mortality for these bears. Illegal kills were documented on both study areas, and many of the unexplained losses were probably due to illegal kills followed by destruction of the transmitters. We were unable to verify any of these possible mortalities, therefore these possible rates should be viewed as maximum rates.

Interpretation of population trend also will be improved by actual data on bear mortalities resulting from depredation and nuisance situations. Currently, NMDGF data are incomplete and do not represent a concerted effort to assess the impact of these actions on bear populations.

Because reproductive success and recruitment are determined largely by mast production, people primarily alter black bear population growth through human-caused mortality of adult and subadult bears. Use of the bear population model with reproductive and survival rates observed during this study indicated study populations were stable (SSA) or slightly increasing (NSA) with a likely annual population increment of no more than 2-4% growth per year on average. If management goals are to maintain bear population levels, strategies that emulate demographic rates observed during this project are appropriate. If management goals are to accomplish strategic changes in numbers or redistribution of bears (e.g., reduce or increase total population, different regional population objectives), then management strategies will call for altering mortality rates up or down from those observed during this study. Options related to those goals can be explored using capabilities of the bear population model.

If annual mast surveys are continued long-term, in addition to providing annual information necessary for model inputs, they also will provide valuable information on the relative frequency of mast failures within different regions of

New Mexico. This information will be useful for determining the growth potential of distinct bear populations within the different regions of New Mexico.

Population Estimation

Two independently derived population estimates (bear population model and habitat extrapolation) put the New Mexico statewide bear population at approximately 5200-6000 bears. These estimates were for the pre-mast season (May-early August) and excluded cubs of the year.

Statewide population estimates derived from this study refute previous estimates. Our estimates indicate a statewide population of approximately twice the long-standing estimate of 3,000 bears previously used by the NMDGF. However, these estimates do not suggest a doubling of the bear population in the past decade. Rather, these estimates are based on better information including demographics, density, and habitat extent.

Population estimates must be used advisedly because each method of population estimation has intrinsic limitations and firm numbers can never be achieved. Furthermore, population estimates derived from the field study represent density in good habitat, and little is known about the relative density of bears found in less suitable habitat. With this new information NMDGF has additionally recognized latitude in bear management, but should proceed with caution regarding adjustment of harvest goals near the upper limit of new estimates without further testing of the model and predictive scenarios.

Estimates of black bear density and total population provide a reasonable estimate of the upper limit of New Mexico bear populations. As an input into the bear population model, this information is intended as a planning figure. While it is not exact, it illustrates that there is an upper limit to the possible statewide bear population and ensures a level of reality prohibiting predictions of unlimited population growth.

Hunt Management

Annual bear kill by hunters was affected by many factors including season timing, hunter effort, hunter method, and mast production, as well as underlying population composition. Hunters aided with dogs had higher success rates and harvested 4 times as many female bears per hunter as those not using dogs. Harvest was positively associated with hunter effort (higher harvest with greater effort), while harvest was negatively associated with mast production (higher harvests with lower mast abundance). Knowledge of these relationships may aid the NMDGF in selecting among various hunt management options.

During the intensive fall foraging period, study bears commonly increased activity patterns and made frequent long-range movements outside of their

primary home ranges. Differences in movement patterns were observed between regions and among different sex and age categories. Movement patterns also differed relative to availability of mast, primarily acorns. Knowledge of these movement patterns may allow the NMDGF to set fall seasons at times most appropriate to accomplish various harvest objectives.

Bears entered dens as early as September and as late as February. Differences in den entry dates were observed between pregnant female and other bears and between regions of New Mexico, however much overlap occurred between sexes and varied annually. Knowledge of these differences will allow the NMDGF to influence the sex and age composition of the harvest to achieve desired management objectives, such as protection of adult females as the reproductive segment of the population. Analysis of pelt tag records indicates later timing of fall seasons reduced harvest of female bears.

Bears emerged from dens as early as March and as late as May. Slight differences in den emergence dates were observed between male and female bears, indicating careful timing of an early spring season could reduce vulnerability of female bears, especially those with new cubs. Analysis of pelt tag records showed spring harvests were dominated by male bears. However, immobility of cubs immediately following den emergence increases the potential for separation of cubs from their mothers (preventing identification of females with cubs), thus orphaning and inevitable cub mortality. Considering both factors, it appears that any spring hunting season will have the potential for reducing cub survival.

Knowledge of black bear denning dates is useful for interpreting sex and age composition of the harvest. The verified differential in den entry and emergence dates among sex and age groups has application to setting bear hunting seasons to accomplish various objectives. However, den entry and emergence dates are highly variable and generally span a period exceeding 2 months. We observed variation relative to mast production; other factors undoubtedly play a role influencing the timing from year to year. No single timing scenario is appropriate for every use.

It is important to recognize that there was no legal hunting on the NSA during 1992 through 1997. Therefore the hunting mortality rates observed may not reflect actual mortality of bears from hunting in northern New Mexico. The possibility of total mortality exceeding the rates we observed must be considered when interpreting harvest data and output from the bear population model.

Habitat Considerations

Estimated statewide bear habitat encompasses approximately 14.6 million acres, of which 75% is primary habitat. Primary habitat represents about 13.5% of the state.

Within predicted bear habitat, mast producing land cover types were found within 7 km (female mast season activity radius) of primary habitat throughout New Mexico except for about 300 km² in the Sangre de Cristo complex. This indicates that nearly all bears have access to habitat with important mast-producing species. However, actual abundance of oak, juniper, and pinyon is unknown within bear habitat because current data are not adequate to assess detailed distribution of potential mast production. Better information on actual mast-species abundance may allow for better interpretation of habitat quality and its potential for bear productivity.

Dens that facilitate security and energy conservation during hibernation period are of significant value to black bears, and female bears exhibit a tendency to select tree cavity dens when available. Retention of large diameter live trees, large snags, and large fallen logs may be a valuable goal in all forest management plans and programs.

Nuisance and Depredation Resolution

Approximately 17% of bear habitat is situated within 5 km of human populations. Availability of garbage and other human-related foods is associated with increased nuisance and depredation activity by bears. Despite the significant potential for conflict, analyses indicated only a minority of bears engaged in nuisance or depredation activities. Nonetheless, kills resulting from bear-human conflict represent a significant mortality factor within the bear population. Efforts to reduce accessibility of human-related foods will be instrumental in reducing the likelihood of bear problems in areas with human populations.

Translocation of bears, as a means of solving depredation and nuisance problems, has shown variable success. Observed homing behavior of adult bears indicates translocation of adult bears is merely a short-term solution, particularly if attractants are not removed from the original site. However, short- and long-term settlement was observed among translocated subadult bears, indicating relocation of subadult bears into remote areas, with little potential for human conflict, may be an effective management tool. Nonetheless, translocation of problem bears should not be done without associated attempts to eliminate or reduce accessibility to human-related attractants (e.g., garbage, pet foods, wildlife feeding, bee hives) where such attractants exist.

APPENDICES

This section contains and references a variety of more lengthy context information regarding the black bear investigation in New Mexico. This section also identifies information in various digital formats and indicates how that information is delivered in final form.

In some cases, digital information are on CDs that reside with New Mexico Department of Game and Fish and U.S. Fish and Wildlife Service Division of Federal Aid. CDs are not provided with every copy of the final report that is printed and distributed.

APPENDIX A: BEAR HANDLING HISTORY, DENNING DATES, AND LOCATION DATA

This appendix represents a tabulation of field data regarding capture and handling histories of individual study bears (StudyBearHistory), den entry and emergence data (DenningDates), and bear locations derived from telemetry monitoring (BearLocations). This appendix is 3 extensive Excel spreadsheets with metadata that are included as data files on a CD-ROM deposited with NMDGF and USFWS as part of the electronic deliverables. A brief example of the file formats for each of the 3 files follows:

StudyBearHistory file format

Age Class	Age	Date	Event	Transmitter Status	Reproductive Status
SA	4	9/24/1992	Capture	New collar	
SA	4	9/26/1992		Shed collar	
SA	3	9/1/1992	Began monitoring	Collar OK	
SA	4	1/13/1993	Handled in den	New collar	No offspring
AD	5	3/22/1994	Observed in den	Collar OK	No offspring
AD	6	3/27/1995	Handled in den	New collar	2 cubs (F690, F691)
AD	7	2/19/1996	Handled in den	Collar OK	1 yearling (F691)
AD	8	3/23/1997	Handled in den	New collar	2 cubs (M284, F674)
AD	9	3/22/1998	Observed in den (inaccessible)	Collar fit unknown	2 yearlings (M284, F674)
AD	9	8/20/1998	Recapture	Collar OK	
AD	10	3/22/1999	Handled in den	New collar	2 cubs (F656, F657)
AD	11	2/18/2000	Handled in den	Removed collar	2 yearlings (F656, F657)
AD	8	9/1/1992	Began monitoring	Collar OK	
AD	9	3/11/1993	Handled in den	New collar	2 cubs (F513, F601)
AD	10	2/7/1994	Handled in den	Collar OK	1 yearling (F513)
AD	10	6/9/1994	Recapture	Collar OK	
AD	10	9/17/1994	Mortality (hunter kill)	Collar OK	
AD	8	9/1/1992	Began monitoring	Collar OK	
AD	9	3/13/1993	Handled in den	New collar	1 cub (M201)
AD	10	2/5/1994	Observed in den	Collar OK	1 yearling (M201)
AD	11	3/17/1995	Handled in den	New collar	2 cubs (M296, M297)
AD	12	2/20/1996	Handled in den	Collar OK	1 yearling (M296)
AD	12	9/2/1996	Mortality (hunter kill)	Collar OK	
AD	10	9/1/1992	Began monitoring	Collar OK	
AD	11	3/15/1993	Handled in den	New collar	3 cubs (M135, M136, F514)
AD	12	2/9/1994	Handled in den	Collar OK	3 yearlings (M135, M136, F514)
AD	13	3/23/1995	Handled in den	New collar	3 cubs (M295, F692, F693)
AD	13	5/12/1995	Mortality (possibly killed by bear)	Collar OK	
SA	3	9/1/1992	Began monitoring	Collar OK

APPENDIX B. GIS AND DATA FILE LISTING AND METADATA

This is an index to the GIS coverages and data files that have been compiled for use in the bear project. The metadata for these files consists of the listing in this appendix and metadata records included with the GIS coverages or individual files identified. Metadata for GIS coverages are designed to meet Federal Geographic Data Committee standards and format. The data and metadata are available on a CD-ROM on file with NMDGF and USFWS as part of final electronic deliverables. The following table describes the directory and file structure for accessing coverages and data files.

Folder	Description	Files	File Description	FGDC Metadata Record
ArcView	ArcView projects and files			
		Model2.apr	Programming for habitat model	
		bearfigs.apr	Arc/View programming for Chapter 11 figures	
		studysites.apr	Arc/View programming for study site figures	
		fig11-x.wmf	Chapter 121 figures

APPENDIX C. HABITAT MODEL AND ASSOCIATED COVERAGES

This appendix contains GIS coverages and data files associated with the habitat model generated for black bears in New Mexico and related analyses in context with human interests and population on the landscape.

The files are located on a CD-ROM and are also identified in Appendix B for file reference and metadata access.

APPENDIX D. PELT TAG NOTEBOOK

This appendix contains a year by year summary of pelt tag and hunter card survey data as they pertain to demographic modeling and simulation. This information was compiled by Katherine Green-Hammond. The appendix is included as digital files on a CD-ROM on file with NMDGF and USFWS as a final electronic deliverable.

See the following pages for an example of the Notebook format

CHANGES BEGINNING IN THE 1998 VERSION

The Central mountain range region was split into the Zuni region (units 9 and 10) and the Manzano region (units 8 and 14). Unit 18 was dropped since it is closed to bear hunting.

Ages defining adults and subadults have been changed for all data summaries. Age 4 bears have been reclassified from adults to subadults consistent with the bear study finding that age 5 is the earliest age at which females give birth in New Mexico populations. Consequently, subadults are defined as bears ages 1 to 4, and adults are defined as bears ages 5 and above, for both sexes.

Most of the interpretive comments have been removed from this notebook. Interpretations will be revised in a future revision of the notebook.

CHANGES IN THIS VERSION

Card survey results from the 1997 season, and pelt tags from the 1998 season have been added; ages are not yet available for the 1998 season pelts.

1998 AND 1999 SEASON DIFFERENCES

Prior to 1998, fall hunting began September 1 or earlier. Both 1998 and 1999 fall hunts were late, beginning and ending later than in previous years.

For the 1998 hunting season, major regulation changes were made. The season dates were October 15 - December 15, a change from the previously standard September 1 - October 31. Also, for 1998 only, hunters could not buy bear licenses after the bear hunting season began. The total bear pelt tags reported for 1998 were 148, the lowest statewide total since pelt tag record keeping began in 1978. The numbers of 1998 hunt season licenses sold, 2969, was lower than all years since 1983 except for 1986 (when bear hunting was closed during elk hunting) and 1992 (when license fees doubled for nonresidents).

In 1999, hunting season dates were October 1 - December 15, and licenses could be purchased during the hunt season. Total pelts increased to 213.

WHAT PELT DATA SUGGEST ABOUT NM BEAR POPULATIONS

Bear populations have gradually increased statewide in the last 30 years. Very high harvests in 1994 and 1995, especially of females, probably interrupted the increasing trend.

The total harvest and, presumably, the hunting mortality rate on bears, were unusually high during 1989 - 1990 and 1993 -1996, possibly because dry environmental conditions increased vulnerability to hunting.

Total statewide harvest peaked in 1994, dropped steadily through 1998, and increased again in 1999. The very low harvest in 1998 can be attributed to the change to a late fall season and very low license sales.

The high numbers and proportions of adult females harvested in recent years may represent the beginning of a period of excessive harvesting, and should be watched.

IMPORTANCE OF HARVEST DATA

Information on bears is very hard to get. Harvest data provide the only information on bears statewide and over time.

Complete pelt tag data (mandatory reporting) substantially reduces the uncertainty about bear harvests, for a reasonable cost.

Tooth age data (one tooth from each pelt) is essential for identifying subadults. Identifying subadults allows pelt data to provide information on good and bad reproductive years, and allows more useful interpretation of changes in total pelt tag numbers.

The bear hunter card survey provides the only information on the geographic distribution of hunting effort and success.

CAUTIONS ABOUT CARD SURVEY DATA

Statewide bear card survey returns number in the hundreds, but there are very few responses reporting hunting or killing a bear in many of the individual game management units. Consequently projections by unit, which are summed for the regional numbers included in this notebook, may be based on unacceptably small sample sizes. The card survey provides the only available information on

geographic distribution of hunting effort, so the unit analysis results have been used in spite of the sample size problem.

The projected total statewide bear kills from the card surveys are usually higher than reported pelt tags, sometimes substantially higher. This may be a consequence of higher return rates from successful than from unsuccessful hunters (we are in the process of testing this hypothesis). Because pelt tag reports are mandatory, the pelt tag numbers are considered to be a more reliable estimate of bear kills than the survey projections. Consequently, survey results are used only for estimates of number of hunters (hunting effort) in this notebook. Number of kills, either reported directly or used in calculations of success rate, are based on pelt tag reports.

TABLE 1. Bear pelt tag numbers over time, ranked by total pelts recorded from 1978 through 1997.

Unit	Total Pelts 1978 - 1997	Annual Average # Pelts 1978 - 1992	Annual Average # Pelts 1993 - 1997

APPENDIX E. CD-ROM WITH BEAR POPULATION MODEL SOFTWARE, SCENARIO LIBRARY, AND USER MANUAL

This appendix consists of model software and other tools associated with preparation and use of the Bear Population Model as compiled by Katherine A. Green Hammond. The information in final form is a set of electronic files on CD-ROM on file with NMDGF Santa Fe state office and USFWS Division of Federal Aid in Albuquerque.

See the following pages for an example of the format of the User Manual.

**This information also is on a CD-ROM distributed with selected
copies of the completion report**

APPENDIX F. BEAR POPULATION MODEL CORE EQUATIONS DOCUMENTATION

This appendix contains the mathematical background for the Bear Population Model. The appendix was compiled by Katherine Green-Hammond and is contained on a CD-ROM provided as a final electronic deliverable.

An example of the text of this documentation is presented on the following pages. It is presented in Times New Roman font to preserve the format as prepared in original form. The version on the CD must be accessed for full understanding and use.

BEAR MODEL CORE EQUATIONS

POPULATION / ENVIRONMENT / HUNT MODEL DESIGN

The bear model tracks changes in population numbers and age and sex composition over time based on computed births, deaths, and migrants. Initial population, characteristic vital rates, and annual variations in mast conditions, den entry timing, and hunting regulations and effort are inputs. An upper limit on population size is optional.

Parturition and cub survival rates vary annually, as a function of mast conditions. Characteristic or average mortality rates are specified for yearlings, subadults, and adults of both sexes. Rates from natural causes, legal hunting, and other human causes are specified separately and are additive. Legal hunting mortality can vary annually, with the characteristic rate modified by hunting effort or increased by poor mast conditions. Hunting mortality for late hunting seasons (beginning in October) is also a function of den entry timing.

Birth and mortality rates are not explicit functions of density dependence or social structure in this model. Optional upper limits on total population and total adult females approximate density dependence at high population levels. Since a hunted population is being modeled, natural mortality rates will be low and hunting mortality is additive rather than compensatory. If there is a need to model long time periods without hunting, natural mortality rates in the absence of hunting should be modified. Migration is treated as a net gain or loss of 3 year old (subadult) males, and is a function of the proportions of males and females in the prehunt population. Immigration occurs when the proportion of males is below a specified threshold. Migration occurs when the proportion of males exceeds a specified threshold.

The model should be applied to a geographic area that is meaningful to bears and managers, from a game management unit to a mountain range. Migration of subadults applies to the modeled area and its surroundings, not movements within the modeled area.

The model bear population structure tracks females and males separately in age classes of cubs, yearlings, subadults (2, 3, and 4 year olds are separate age classes), and all adults (ages 5 and up) lumped. The age structure allows the influence of strong and weak cohorts to be expressed over time, and tracking of recruitment to breeding age. No maximum age is imposed or tracked in simulations; long term average total annual mortality rates determine model population longevity.

The adult female category is divided into groups with cubs, with yearlings, and with no offspring in dens. The birth rate model includes the alternate year breeding pattern of black bears; adult females with yearlings in dens are not eligible to produce cubs. The phenomenon of synchronized breeding can be simulated by the model under appropriate conditions. Adult females with cubs in the fall are partially vulnerable to legal hunting.

The effectiveness of the regulation protecting females with cubs from hunting mortality is a variable.

The model biological year has 3 parts, denning, active season spring and summer, and active season fall. Births take place during denning. Natural and other human caused mortalities occur during both active seasons. Hunting mortality occurs only during the fall season in the current model version. A spring hunting season may be added in a later version.

CORE MODEL RELATIONSHIPS: CALCULATION ENGINE

Timing and Sequence of Events

The initial population is post hunt numbers by sex and age category at the time of den entry at the end of the fall active season. The bear model year is a calendar year and begins with the winter denning season.

For age tracking throughout a simulation run, all birthdays occur at the beginning of the year, in dens, but before births. Each model year, including the first, begins with age updating; cubs at den entry become yearlings, and adult females with cubs at den entry are reclassified as adult females with yearlings at the beginning of the simulation year, and are not eligible to produce cubs that year. Bears aged 1, 2, 3, and 4 the previous year become ages 2, 3, 4 and adult (all yearlings become subadults, some subadults become adults); adults aged 5+ remain adults. New age 5 females are classified as adult females with no offspring in the den, and are eligible to produce cubs. Adult females with yearlings at the end of the previous fall are reclassified as adult females with no offspring, and are eligible to produce cubs. Adult females with no offspring at the end of the previous fall remain adult females with no offspring, and are eligible to produce cubs.

At the beginning of the year, with updated ages, there are no adult females with cubs, and the male and female cub categories are empty. All births, but no mortalities, occur during the denning season. All mortalities, but no births, occur during the early and late active seasons.

Environmental variation

The environmental condition variables of mast index, hunt effort, hunt season start date (or hunt closure), and den entry timing are inputs which may change from year to year. All vital rates are simple functions of the environmental variables modifying an underlying rate treated as a population characteristic. Variation in the environmental variables results in variation of the vital rates.

Vital rates: Characteristic rates with variation

Parturition rates and cub survival rates have input characteristic values associated with poor, fair, and good mast conditions, as well as values for special cases and long term average values. Fall mast condition (or special case or average values) is an input which may vary by year, forcing parturition and cub survival to vary by year correspondingly. Functions of mast condition involve time lags; mast index for a year influences cub survival for the same year, and parturition rate for the next year. Mortality rates have characteristic values for each combination of age, sex, and cause, which are constant and specified as inputs. Variation in mortality rates from year to year is handled by multiplying the characteristic rates by factors which are functions of mast condition, hunt effort, hunt regulations, and den entry timing.

Notation for Representing Population Numbers

F0, F1, F2, F3, F4, AF number of females of age 0 (cubs), 1, 2, 3, 4,
adult

M0, M1, M2, M3, M4, AM number of males of age 0 (cubs), 1, 2, 3, 4,
adult

CUBS = F0 + M0 number of cubs

YF = F1, **YM** = M1 numbers of yearlings for each sex

SF = F2 + F3 + F4 number of subadult females

SM = M2 + M3 + M4 number of subadult males

AFnone number of adult females without cubs or
yearlings

AFcubs number of adult females with cubs

AFyrl number of adult females with
yearlings

AF = AFnone + AFcubs + AFyrl

Top-down effects of apex predators are modulated by human impacts on community composition and species abundances. Consequently, research supporting top-down effects of apex predators occurs almost entirely within protected areas rather than the multi-use landscapes dominating modern ecosystems. Here, we developed an integrated population model to disentangle the concurrent contributions of a reintroduced apex predator, the grey wolf, human hunting and prey abundances on vital rates and abundance of a subordinate apex predator, the puma. Increasing wolf numbers had strong negative effects on puma fecundity, and subadult and adult survival. Puma survival was also influenced by density dependence. Overall, puma dynamics in our multi-use landscape were more strongly influenced by top-down forces exhibited by a reintroduced apex predator, than by human hunting or bottom-up forces (prey abundance) subsidized by humans. Quantitatively, the average annual impact of human hunting on equilibrium puma abundance was equivalent to the effects of 20 wolves. Historically, wolves may have limited pumas across North America and dictated puma scarcity in systems lacking sufficient refugia to mitigate the effects of competition.

1. Introduction

The reintroduction of large carnivores to areas in which they were previously extirpated has provided opportunities to study and quantify the top-down effects of apex predators within ecological communities (e.g. [1,2]). The strength of the various ecological effects of apex predators, however, is modulated by jurisdiction and appears to be obscured in unprotected landscapes where they are overshadowed by human impacts on community composition and species abundances [3–6]. Human activities and social tolerance for large carnivores, for example, determine carnivore distribution and abundances [7], and therefore the potential strength of top-down effects attributable to apex predators in most ecosystems. Further, human agricultural practices subsidize lower trophic levels and increase bottom-up effects in many modified systems [4,8]. For these reasons, results demonstrating strong top-down effects of apex predators on subordinate predators and their prey almost entirely come from studies conducted inside protected areas rather than the much more common multi-use landscapes dominating modern ecosystems [4,5,9].

Traditionally, ‘top-down effects’ described effects across trophic levels, but more recently they have also been used to describe the effects of dominant competitors on subordinate competitors that share trophic levels in more complex food webs (e.g. [10]). Pumas (*Puma concolor*) are subordinate, wide-ranging, solitary carnivores and their population dynamics exemplify the difficulties

in differentiating top-down from bottom-up effects. Pumas live at low densities and exhibit life histories typical of long-lived species, making it difficult to obtain sample sizes needed for complex analyses aimed at understanding drivers of their population dynamics [11]. Contemporary puma population dynamics in western North America are also dominated by anthropogenic top-down effects in the form of legal hunting [12,13] and other anthropogenic impacts (e.g. road mortality, conflict management and depredation permits [14]). Like other apex carnivores, theory predicts that the abundance of pumas in areas without human hunting is determined by prey availability [15–17]. Pumas, however, are also subordinate to four dominant competitors across their range: grey wolves (*Canis lupus*), grizzly bears (*Ursus arctos*), American black bears (*U. americanus*) and jaguars (*Panthera onca*) [18]. These species compete with pumas for prey, usurp their kills (i.e. kleptoparasitism) and sometimes kill them. Therefore, pumas are clearly susceptible to additional top-down forces beyond those exerted by humans. Evidence suggests that grey wolves, in particular, impact numerous puma behaviours, including puma habitat use and prey selection [19,20], but researchers still lack direct evidence that wolves affect the abundance of pumas on the landscape [18].

Wolves were reintroduced in Yellowstone National Park in the USA in 1995, shortly after which they expanded into adjacent multi-use landscapes. Between 2000 and 2015, the puma population in the southern Greater Yellowstone Ecosystem (GYE) declined by 48%, as explained by three primary causes of mortality: regulated human hunting of adult and subadult pumas, grey wolves killing puma kittens, and increased starvation across age classes, but especially subadults [21]. The southern GYE is a mosaic of variable human perturbations influencing local wildlife, including legal hunting of predators and ungulates, and subsidized primary production through watering grasslands and agriculture on private ranches and public lands. Wildlife managers also subsidize bottom-up effects through supplemental feeding programmes on public lands aimed at supporting wintering elk (*Cervus canadensis*) populations and mitigating elk conflicts with local ranchers [22].

Here, we combine 16 years of monitoring data from 147 individual pumas, their associated estimates of survival and fecundity, as well as abundance estimates of pumas, wolves and prey (elk) in an integrated population model (IPM) to link observed patterns of mortality with declines in puma abundance. Integrated population models provide the opportunity to include multiple types of data and allow researchers to simultaneously examine the abundance and demographic drivers underlying changes in abundance [23,24]. Such insights will support conservation management of pumas and wolves, given the current expansion of both species in North America due to reintroduction efforts for wolves and the evolution of wildlife management encouraging coexistence strategies with large carnivores following the cessation of predator bounty hunting. Such work may also prove useful in deciphering historic ecological systems in North America, when pumas and wolves were sympatric across nearly all of the puma range. Recent research has highlighted that coyote (*C. latrans*) expansion in North America, for example, is in part due to wolf eradication efforts that occurred a century ago [2,25].

Based upon research in other carnivore guilds highlighting the impacts that dominant competitors have on the abundance of subordinate competitors (e.g. African lion (*Panthera*

leo) and wild dog (*Lycaon pictus*) [26]; tiger (*Panthera tigris*) and leopard (*Panthera pardus*) [27]; wolf and coyote [25]), we predicted that reintroduced wolves would have a population-level effect on puma abundance. To begin with, we accounted for the effects of human hunting on pumas that might obscure wolf effects. Then we tested several *a priori* models to determine whether top-down (human hunting or wolf abundance) or bottom-up (prey abundance) or some combination of top-down and bottom-up forces best fit puma vital rates and changes in puma abundance determined over 16 years of fieldwork (the time period during which wolves completely recolonized the study area). Finally, we used the most parsimonious model explaining observed fluctuations in puma population size to project future potential puma populations in the region, essential for the conservation of this charismatic predator and the maintenance of its diverse contributions to healthy ecosystems [28–30].

2. Methods

(a) Study area and wolf reintroductions

Our research ran from late 2000 until 2017, and our study area encompassed approximately 2300 km² of the southern GYE in northwest Wyoming, USA, northeast of the town of Jackson (figure 1; WGS84 43.60671, -110.41182). Our study area overlapped different types of public lands reflecting various, species-specific management. To the west, the study area included approximately 475 km² of the Grand Teton National Park, where wildlife were fully protected, except elk, which were subject to an Autumn hunt in managed subsections of the National Park. To the south, wildlife were also fully protected on the 100 km² National Elk Refuge (NER), except bison (*Bison bison*) and elk, which were subject to limited harvest during an Autumn hunt. The remaining 75% of the study area was composed of lands managed by the United States Forest Service (USFS), which allowed legal hunting and trapping of diverse mammals following guidelines set by the Wyoming Game and Fish Department (WGFD). This included hunting of carnivores and competitors, including American black bears and coyotes, and ungulate prey, including elk, mule deer (*Odocoileus hemionus*), moose (*Alces alces*), pronghorn (*Antilocapra americana*) and bighorn sheep (*Ovis canadensis*). Grizzly bears were fully protected during the study, except bears killed due to human safety or livestock conflict issues on public or private lands.

Wolves were first reintroduced north of our study area in Yellowstone National Park in 1995 [31]. The first breeding pair settled in our study area in 1999, and annual estimates for the numbers of wolves and wolf packs in the study area have since been determined by the United States Fish and Wildlife Service (USFW). Wolves were protected from legal hunting during our study excepting 2012 and 2013, when a limited quota hunt was permitted from October 1 to December 31 of each year. Over the duration of our research, the number of wolves in the study area ranged between 10 and 91 individuals, the peak of which occurred in 2010 [21].

Elk in our study area were part of the migratory Jackson herd and cooperatively managed by the WGFD, National Park Service and the NER. Portions of the Jackson elk herd travel long distances, but the entire herd congregates near Jackson, in winter, where they receive supplemental feeding on the NER and adjacent USFS lands on feed lots managed by the WGFD. Our study occurred during the time period in which managers implemented liberal hunting quotas across jurisdictional boundaries to reduce the Jackson herd from 16 000 in 2000 to 11 000 animals [22,32].

Figure 1. The location of our study area in northwest Wyoming in the USA in the inset, and a larger map delineating land ownership. The rectangle is the portion of the study area in which we annually captured pumas. (Online version in colour.)

Our study area also included large private inholdings surrounded by public lands (e.g. ranches), as well as development on the fringes of local communities, all of which subsidized primary production directly through agriculture (hay or alfalfa or other crops), watering pastures for livestock or lawns, and/or feed provisioning meant for livestock but used by wildlife. Additional descriptions of climate, topography and habitat are presented in Elbroch *et al.* [33].

(b) Puma captures, monitoring and age classifications

We included puma monitoring data beginning in 2001, when a sufficient proportion of the population had been captured to justify analyses. We followed puma capture and immobilization protocols described in Elbroch *et al.* [33] and approved by the Jackson Institutional Animal Care and Use Committee (Protocol 027-10EGDBS-060210) and National Park Service IACUC (Protocol IMR_GRTE_Elbroch_Cougar_2013-2015). Pumas were fitted with a VHF (Telonics, Mesa, AZ) or GPS (Telonics, Mesa, AZ; Televilt, Lindesberg, Sweden; Vectronics, Berlin, Germany; Lotek Wireless, Ontario, Canada) collar. We counted kittens in known dens, when possible within 3 weeks of their birth, and then hand-captured kittens between 5 and 7 weeks old without the aid of immobilization drugs. Any kittens we managed to capture were fitted with custom-made, lightweight, expandable VHF collars (Telonics, Mesa, AZ).

We attempted to locate kittens wearing VHF collars every 2 days until they were 10- to 12-months old, when collars dropped

on their own. All other pumas wearing VHF collars were located at minimum weekly from the ground and monthly from aircraft. Location data were acquired by GPS collars 4–12 times per day. All collars were equipped with mortality sensors, which alerted researchers when an individual had not moved for greater than or equal to 8 h. We investigated mortality sites and determined the cause of death through interpreting field signs (e.g. bite marks, footprints), necropsies conducted with a veterinarian and based on blood and tissue samples analysed by the Wyoming Game and Fish Wildlife Health Laboratory [34].

(c) Estimating annual puma density

Each year, we determined the minimum puma density in our study area based on overlapping home ranges [35]. Annual home ranges for adult pumas were determined using fixed-kernel density estimators [36] in ArcGIS 10, and isopleth calculations in the Geospatial Modeling Environment [37]; methods are further described in Lendrum *et al.* [38]. We determined the boundaries of the area in which we consistently searched for pumas each winter, and in which we believed we had captured all resident pumas. In ArcGIS 10, we created a polygon of our capture area and quantified each puma's residency within this polygon [35]. 'Minimum puma densities' (i.e. excluding transients or residents we did not capture) were then determined by summing the residency estimates for all adult pumas with overlapping home ranges for each year. Kitten estimates were those kittens that accompanied marked, resident females we monitored.

(d) Integrated population model

We estimated future puma abundance using a demographic model inclusive of seasonal fecundity and stage-specific survival rates operating on a six-month time step. Following Elbroch *et al.* [21], we split each year into two six-month seasons, one in which there was regulated legal hunting for pumas, and the other during which hunting was not permitted. These seasons captured variation in effects due to human-caused mortality as well as other mortality: (i) pumas were legally hunted during a ‘hunting season’ running from 1 October to 31 March of the following year. The hunting season also captured additional ecological variation: elk migrations to low-elevation winter ranges where they aggregated in large herds near supplementary feeding stations, mule deer migrations out of the study area, increased competition between wolves and pumas, and deep snows and cold temperatures influencing puma movements and energetics [20]. (ii) Puma hunting was closed during the ‘non-hunting season’ from 1 April to 30 September of each year, during which elk migrated to high-elevation summer ranges and spread out, mule deer returned to the study area, temperatures warmed, and ungulate and puma parturitions occurred [21,38].

We defined puma life-history stages based on differences in behaviour and survival reported in the literature. We defined kittens as 0–6 months, subadults as 7–18 months and adults as greater than or equal to 18 months of age. Kittens (defined as stage K) were completely dependent on their mothers and experienced high mortality from both predation and starvation [39,40]. Subadults were dependent on their mothers, less susceptible to predation [39], but more susceptible to starvation. Subadults could be legally hunted once they were 1-year old and separate from their mothers [41], and they experienced additional risks associated with dispersal [11,42]. While we assumed that all subadults had the same vital rates, we distinguished between subadults less than a year old that could not be hunted (defined as stage $S1$) from older individuals that could be hunted (defined as stage $S2$). We pooled all individuals greater than or equal to 18 months old into an adult age class (defined as stage A) when pumas were expected to establish stable territories and become reproductively active [11,39].

Our models assumed a birth pulse in the non-hunting season [38], thus fecundity was only modelled for the non-hunting season. We did, however, allow some kittens to recruit the following non-hunting season, to better reflect the fact that kittens may be born late in the non-hunting season, and on occasion, at the onset of the hunting season [43]. We modelled the number of kittens that recruited at the end of the non-hunting season as a fixed proportion, π , of the total number of kittens birthed in that calendar year.

Survival probabilities were informed by integrating an abundance model with a multistate capture–mark–recapture model. The abundance model described the seasonal abundances as log-normal random variables. The mean of each was modelled using the transition matrices described in equations (2.1) and (2.2). We modelled the variance of the abundances using a stage-specific variance term that can be interpreted as the environmental variation experienced by each stage [44]. The capture–recapture data was modelled using a multistate survival model that accounted for death due to legal hunting, or death due to other causes, hereafter ‘other mortality’. Other causes of death in our study included starvation, disease, predation, poaching, capture-related mortalities and undetermined mortality [21]. We allowed harvested animals to remain in the model until the end of the six-month harvest period to compete for resources but removed these harvested individuals from the reproductive pool so that they were not producing offspring.

The survival models for each stage and season were coupled to a fecundity model in a stage-structured matrix [45] to quantify seasonal changes in population abundance. A life cycle diagram describing all possible state transitions is given in the electronic supplementary material, figure S1. We denote the natural survival terms in the model as ϕ , with a subscript indicating the life-history stage and season, harvest probabilities as p_{harvest} , and fecundity as f . Kittens (stage K) were surveyed soon after birth, so we were able to estimate true fecundity; all other stages were surveyed at the end of each census period. Our model for the non-hunting season in year y included the birth pulse of kittens, the survival of subadults and adults, and recruitment of all stages. In equation (2.1), we assumed that kittens recruited to become subadults with probability π , accounting for the fact that some proportion of kittens may be born late in the non-hunting season, and on occasion, at the onset of the hunting season.

The hunting season model was similar to the non-hunting season though it did not have any fecundity term (equation 2.2). We modelled annual natural survival rates ($\phi(y)$) using a logit link that incorporated covariates associated with each of our hypotheses (described below). Recapture (i.e. detection) probabilities were modelled with year (y) as a random effect. Individuals that dispersed from the study area during the study were censored.

Integrated population models are robust to some assumptions (e.g. dependence of abundance and recapture data [46]), but fragile to others, such as tag-loss [47]. We only had one dropped collar over the course of the study, and we accounted for heterogeneity in mortality with a stage-structured model. Transient individuals that are never monitored and only spend a short time in the study area also have the potential to increase intraspecific competition that could bias model outputs. However, in a land-tenure species like pumas [15], we expect that

$$\begin{bmatrix} K_{\text{non}} \\ S1_{\text{non}} \\ S2_{\text{non}} \\ A_{\text{non}} \end{bmatrix}_y = \begin{bmatrix} 0 & 0 & 0 & f \\ \phi_{K,\text{hunt}} \cdot \phi_{S,\text{non}} \cdot (1 - \pi) & 0 & 0 & 0 \\ 0 & \phi_{S,\text{non}} \cdot \pi & 0 & 0 \\ 0 & 0 & \phi_{A,\text{non}} \cdot (1 - \pi) & \phi_{A,\text{non}} \cdot \pi \end{bmatrix}_{y-1} \begin{bmatrix} K_{\text{hunt}} \\ S1_{\text{hunt}} \\ S2_{\text{hunt}} \\ A_{\text{hunt}} \end{bmatrix}_{y-1}. \quad (2.1)$$

$$\begin{bmatrix} K_{\text{hunt}} \\ S1_{\text{hunt}} \\ S2_{\text{hunt}} \\ A_{\text{hunt}} \end{bmatrix}_y = \begin{bmatrix} (1 - \pi) & 0 & 0 & 0 \\ \phi_{K,\text{non}} \cdot \phi_{S,\text{hunt}} \cdot \pi & 0 & 0 & 0 \\ 0 & \phi_{S,\text{hunt}} \cdot (1 - p_{\text{harvest}}) \cdot (1 - \pi) & 0 & 0 \\ 0 & 0 & \phi_{A,\text{hunt}} \cdot (1 - p_{\text{harvest}}) \cdot \pi & \phi_{A,\text{hunt}} \cdot (1 - p_{\text{harvest}}) \cdot (1 - \pi) \end{bmatrix}_y \begin{bmatrix} K_{\text{non}} \\ S1_{\text{non}} \\ S2_{\text{non}} \\ A_{\text{non}} \end{bmatrix}_y, \quad (2.2)$$

bias to be minimal because negative effects of competition between residents and transients primarily impact transients.

We considered four continuous covariates as potential drivers of seasonal changes in puma abundances: (i) annual minimum puma densities to test for possible density-dependent effects (estimated as resident adults/890 km²); (ii) annual elk counts for the Jackson herd as reported by WGFD; (iii) annual elk counts of the number of animals wintering off the NER, and which are more reflective of true prey availability for local pumas [48] and (iv) annual wolf counts for our study system, as reported by the USFW (electronic supplementary material, table S1 [21]). Two covariates were different elk metrics representing prey availability and bottom-up effects, as elk abundance had previously proven highly predictive of cause-specific mortality rates for pumas in the study system [21]. We tested for multicollinearity among predictor variables and report them in electronic supplementary material, figure S2.

We used the above covariates to construct six hypotheses about the ecological factors driving puma vital rates: Model 1 (hereafter the 'null model') assumed that all demographic rates in the models defined by equations (2.1) and (2.2) were constant through time. Model 2 (hereafter the 'density-dependent model') varied all vital rates depending upon adult puma densities from the previous season. We constructed three additional models that had density-dependent variables plus one of three covariates representing top-down versus bottom-up effects on puma vital rates: Model 3 included annual wolf counts for our study area as reported by the USFW (hereafter the 'density + wolf model'). Model 4 included annual counts for the Jackson elk herd as reported by WGFD (hereafter the 'density + elk model'), and Model 5 included annual counts of elk in the Jackson elk herd that wintered off the NER as reported by the WGFD and NER (hereafter the 'density + off-refuge elk model'). Model 6 combined elements from these covariates into a hypothesis we generated based on the literature about puma ecology and our own observations in the field. This model included density-dependent and off-refuge elk effects on puma fecundity, wolf effects on kitten survival, and both off-refuge elk and wolf effects on adult survival (hereafter referred to as the 'Local Perceptions' model). We did not include a model with both wolves and elk, because of the high correlations between the variables ($R^2 = 0.71$, 0.78 ; electronic supplementary material, figure S2). Our initial diagnostic figures also illustrated patterns of density dependence in population counts, and therefore, we did not test models without puma density in our initial *a priori* models. However, we did run post hoc models that included the effects of individual covariates without density-dependent effects. We standardized all covariates so that the magnitudes of parameter estimates could be directly compared within and among models.

We modelled survival rate of age class S , season X , in year y (denoted as $\phi_{S,X}(y)$) using a logit model with covariate effects that could include the effects of density dependence and a covariate. This full form of this model was $\text{logit}(\phi_{S,X}(y)) = \beta_{S,X} + \beta_{S,P} \cdot A_X(y) + \beta_{S,C} \cdot C(y)$, where $\beta_{S,X}$ was the intercept term, $\beta_{S,P}$ was a regression coefficient that gives the effect of the adults puma density, $A_X(y)$, in season X and year y , and $\beta_{S,C}$ was a regression coefficient that determined the effect of a covariate, $C(y)$, in year y , on age class S . For the null model, we set $\beta_{S,P} = 0$ and $\beta_{S,C} = 0$, while for the density-dependent model we set $\beta_{S,C} = 0$.

The full annual fecundity model for year y was, $f(y) = e^{\alpha_0 + \alpha_P \cdot A_{\text{Hunt}}(y) + \alpha_C \cdot C(y)}$, where α_0 is the log-fecundity and α_P and α_C were regression coefficients that accounted for the effects of puma adults density in the hunting season and other covariates, respectively. As in the survival model, we set the appropriate coefficients to 0 for the null and density-dependent models. The vital rate models for each of our candidate models are reported in electronic supplementary material, table S3.

All estimates were conducted using MCMC in JAGS [49]. We ran models with four chains, each chain had a burn-in of 10^4

iterations followed by 10^4 draws from the posterior distribution. We determined convergence of the MCMC chains by a visual inspection of each posterior distribution and by examining Gelman's \hat{R} statistic. We used the Watababe-Akaike criterion (WAIC) to rank relative model performance [50].

(e) Projecting future puma populations

We simulated potential puma populations 25 years into the future using parameter estimates from our most parsimonious model under two scenarios. For both scenarios, we simulated the effects of wolf abundance on puma populations, but in only one did we include human harvest. We let wolf abundance range from the minimum observed value (10 wolves in 2001) to the maximum (91 wolves in 2010) over a range of 15 evenly spaced values, assuming that wolf densities were constant over the simulation period. In the first scenario, we included the effect of hunting mortality at historic levels, using the estimated value for the probability of an animal being hunted (p_{Harvest}). In the second scenario, we completely removed the effects of hunting (i.e. we set $p_{\text{Harvest}} = 0$). We simulated dynamics using the mean posterior estimates under each wolf abundance 10^4 times and calculated the mean puma abundance in the hunting season. The population simulations were initiated using the puma population abundances from 2016, the last full year of the study.

3. Results

(a) Puma monitoring

We monitored 147 individual pumas (86 kittens, 22 subadults, 39 adults) and estimated minimum annual puma densities based on 4.5 (1.8 s.d.) adult pumas monitored each year. Adult puma densities in the 890 km² portion of the study area for which we determined density varied between 2.5 and 8.9 resident adults, or 0.28–1.0 adults/100 km² (electronic supplementary material, table S1). Over the course of the study, we recorded 115 mortalities. Eighteen mortalities were from legal hunting, eight of which were censored from the analyses because they dispersed beyond the study area, and 10 pumas were killed by wolves (table 1). Information on annual wolf and elk abundances is found in electronic supplementary material, table S1.

(b) Integrated population model

Our analyses demonstrated that observed changes in population abundance of pumas were best described by a model that included puma density and wolf abundance (density + wolf) as predictors of survival and fecundity (table 2). This model estimated (estimates reported as (mean, probability of direction (p_D) [51]) that both puma density ($\alpha_P = -0.09$, $p_D = 0.99$) and wolves ($\alpha_W = -0.20$, $p_D = 0.98$) negatively affected puma fecundity, and that wolves also negatively influenced adult puma survival ($\beta_{A,W} = -0.36$, $p_D = 0.99$) and subadult survival ($\beta_{S,W} = -0.24$, $p_D = 0.70$); the effects on subadult survival, however, had high uncertainty. We also found that the impact of puma densities on adult puma survival was negative ($\beta_{A,P} = -0.14$, $p_D = 0.99$), consistent with a density-dependent effect on survival. All other covariate effects in these models were near zero and had a p_D less than 0.95. All parameter estimates and credible intervals from this model are reported in electronic supplementary material, table S2. Support for this model garnered more than five times the

Table 1. Cause of mortality for pumas at age of death, as opposed to age at start of monitoring.

empirical support of the second-ranked model that included the effects of puma density and off-range elk [52].

In our best model, we estimated the average annual recapture probability of a puma to be 0.90 (0.17 s.d.). All rates varied substantially between hunting and non-hunting seasons and in some cases by year as well (figure 2). The estimated annual fecundity (reported as posterior mean) was 1.53 (0.51 s.d.) kittens per female per year. Predicted fecundity had substantial temporal variation due to the strong effects of both density dependence and wolves (figure 3). Our six-month survival estimates for kittens were 0.36 (0.10 s.d.) in the non-hunting season and 0.28 (0.08 s.d.) in the hunting season (figure 2b). The subadult survival rates, including only other mortality, were 0.93 (0.10 s.d.) in the non-hunting season and 0.82 (0.17 s.d.) in the hunting season (figure 2c). The adult survival rates, including only other mortality, were 0.90 (0.03 s.d.) in the non-hunting season and 0.86 (0.03 s.d.) in the hunting season (figure 2d). Finally, we estimated the annual probability of mortality in subadults and adults due to hunting as 0.04 (0.02 s.d.).

(c) Simulated future puma populations

Our projections under our best model predicted a threefold (CI 1.4–4.3) decrease in the local puma population over the range of observed wolf abundances (reported as median (95% CI) (figure 4). Removing legal hunting mortality increased puma abundance by approximately 30% (CI –21%–

106%), which translated to roughly two adult pumas at low wolf abundance and one adult puma at high wolf abundance. The relative impact of removing puma hunting corresponded to a change approximately equivalent to removing 20 wolves from the system.

4. Discussion

Our results suggested that puma abundance in the southern GYE is more strongly influenced by top-down forces (i.e. competition) exhibited by a reintroduced apex predator, than by top-down forces exhibited by human hunting or bottom-up forces (prey abundance) subsidized by humans promoting and providing primary production through agriculture and supplemental feeding programmes. Our earlier analytical approach, in which we determined local puma survival rates using multistate capture–mark–recapture models [21], supported previous research emphasizing that top-down forces are obscured by stronger bottom-up forces outside protected areas [4]. Here, our IPM combining vital rates and abundance data provided novel insights into this complex system and helped us further parse out the competitive effects of wolves and the bottom-up effects of elk on different puma age classes. Our modelling framework, in which we separate human hunting from the effects of apex predators, may also allow other researchers to more realistically assess top-down effects outside protected landscapes, where we see mixed human effects and increased bottom-up forces. In the era of the Anthropocene, mixed scenarios occurring along a spectrum of completely protected to completely developed landscapes are increasingly likely to occur [5].

Predominantly, our study system was not protected from wildlife exploitation. Grey wolves, however, were protected in all but 2 years of our study, during which there was limited harvest. Grey wolves are distinctive because they can exhibit strong top-down effects that initiate trophic cascades in natural systems [1,7,53]. In our study, increasing wolf numbers had strong negative effects on puma fecundity, subadult survival and adult survival. These effects were near parallel to effects previously assigned to changing elk densities off the NER rather than wolves in an earlier analysis we conducted with multistate capture–mark–recapture models and a subset of the puma data herein [21]. The effects of increasing wolves and decreasing off-refuge elk, however, are highly correlated and difficult to tease apart ($R^2 = 0.71$; electronic supplementary material, figure S2). In fact, wildlife managers suspect changing elk distributions are at least in part explained by increasing wolves in the system, and that elk are seeking to reduce predation risk from wolves by selecting more open habitat on the NER than they did historically [32].

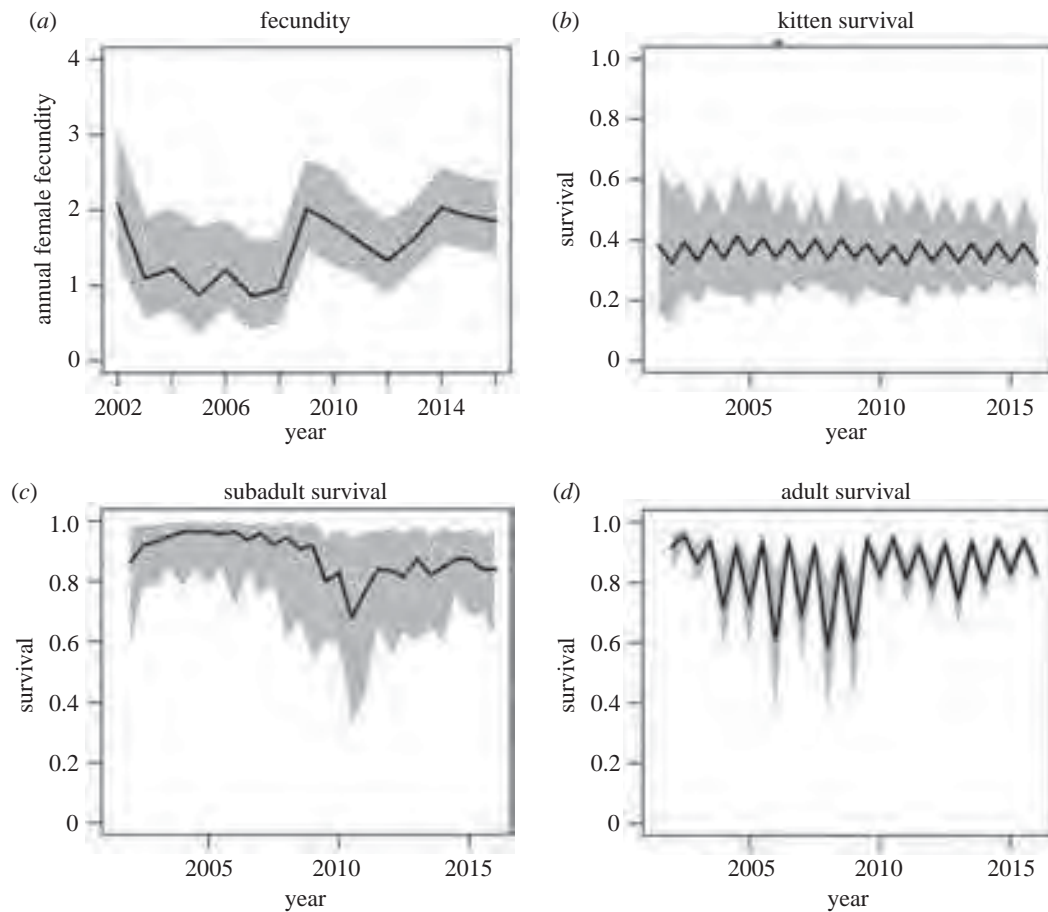

Figure 2. Estimated annual vital rates of pumas throughout the study, excepting hunting mortality. Black lines denote estimated mean, grey shaded area denotes the 95% credible interval.

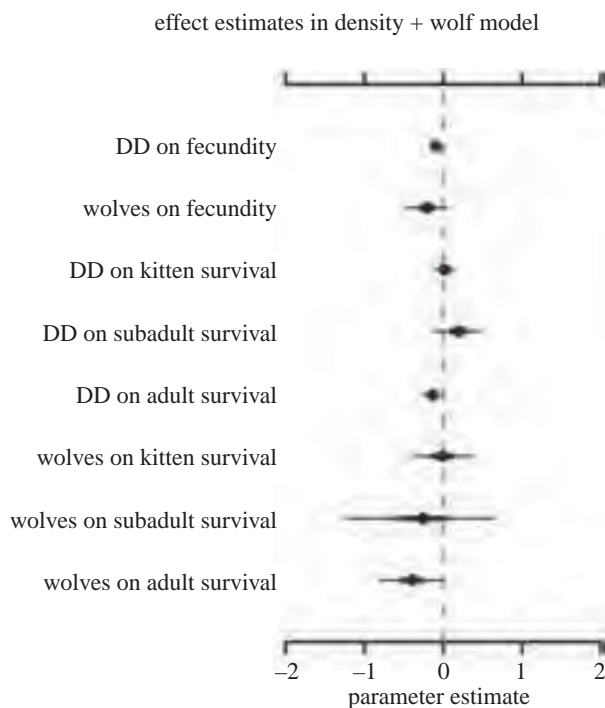

Figure 3. Posterior density estimates for each covariate in the density (DD) + wolf model. Dots denote median estimates, thick horizontal lines denote the 50% credible interval and thin black lines denote the 95% credible interval.

Further evidence for this complexity is found in interpreting the potential cause of puma starvation, which nearly equalled mortality attributed to predation (table 1). Puma starvation

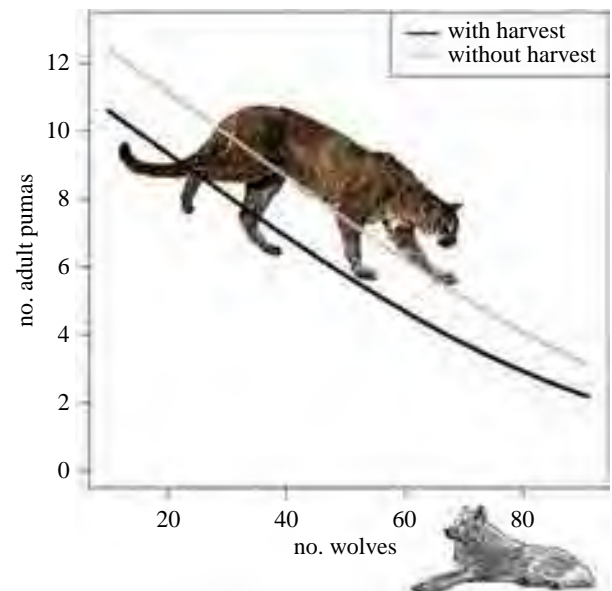

Figure 4. Effect of changing wolf abundance and the effect of hunting mortality on the average adult puma abundance during the hunting season for the 890 km² area for which we estimated puma density.

may have increased over the study due to the declining elk herd (i.e. bottom-up effects), decreased accessibility to elk, as mediated by exploitive and interference competition with wolves (top-down effects), or both [21].

Puma survival was also influenced by density dependence and decreasing puma abundance over the course of the study. Density-dependent effects negatively impacted

Figure 5. A map of North America depicting the historic and current ranges of pumas in green, and the current range in which they overlap with grey wolves in dashed lines. Historically, wolves covered nearly the entirety of North America, excepting southernmost Mexico and Central America. (Online version in colour.)

fecundity as well as adult and subadult survival. Subadult survival appeared to increase with decreasing puma numbers, which is not surprising for a land-tenure species that exhibits territoriality [15]. Given the uncertainty in this estimate (electronic supplementary material, table S2), however, we are cautious about how we interpret this result. ‘Juvenile delinquent theory’ predicts that when hunting removes adult males, the number of independent subadults in puma populations increases, creating unstable social dynamics [54,55], but at this time, it is unknown whether there is a threshold level of hunting that results in these dynamics.

Our results supported previous research emphasizing the additive effects of hunting on puma mortality [12,13]. Uniquely, we were able to estimate that the average annual impact of human hunting on puma abundance in this system was approximately equivalent to the effects of 20 wolves (figure 4). We would emphasize that human hunting was low in our study system as compared to other areas of the USA, and that human hunting does not replace wolf effects. Wolves and human hunting directly and indirectly influence puma sex and age classes very differently. Nevertheless, these results have implications for how we might interpret the current versus historic distribution and abundance of pumas in what was wolf range. It may be that historically, wolves limited pumas heavily across North America, where the species were entirely sympatric except in southern Mexico and Central American countries. Historic wolf abundance may have also dictated puma scarcity in systems lacking sufficient refugia to mitigate the effects of competition (e.g. plains grasslands [56,57]). Further, current puma abundance in parts of western North America may be high not only due to the cessation of puma bounties in the mid-twentieth century, but also to competitive release due to the widespread extirpation of wolves in the USA (figure 5).

Most importantly, our research emphasizes that when hunting is used as a management tool on subordinate

predators in systems with other apex predators, population declines can happen quickly. This is an especially cautionary note for managers in regions where apex predators are recovering or being reintroduced [18]. This puma population dropped by 48% while wolves repopulated the study area and increased in abundance [21]. In another example, leopards decreased by 79% over 4 years as tiger numbers increased; researchers assumed that leopard numbers decreased due to competition reducing leopard foraging opportunities, as well as spatial displacement driving leopards into areas where conflict with people increased leopard mortality [27]. Thus, we recommend that in systems with recovering apex predators, managers evaluate subordinate predator hunting limits preemptively rather than post hoc as they did in our system, to compensate for the effects of dominant competitors on subordinate guild members. In Wyoming, wolf hunting has recently been legalized again, and as an unintended byproduct, this action will likely facilitate the maintenance of a higher density of pumas in the study system.

Ethics. We followed puma capture and immobilization protocols suggested by the American Society of Mammalogists and approved by the Jackson Institutional Animal Care and Use Committee (Protocol 027-10EGDBS-060210) and National Park Service IACUC (Protocol IMR_GRTE_Elbroch_Cougar_2013-2015).

Data accessibility. All data not presented in the manuscript, as well as code for our analyses, are available from the Dryad Digital Repository: <https://doi.org/10.5061/dryad.5qfttdz31> [58].

Authors’ contributions. L.M.E. designed the study, coordinated the study, collected data, participated in data analysis and led the writing of the manuscript; J.F. designed and conducted the analyses, and drafted the manuscript; H.Q. designed the study, coordinated the study and collected data; D.C. designed the study, coordinated the study and collected data; D.T. provided project support and collected data. H.W. participated in data analysis and drafted the manuscript. All authors gave final approval for publication and agree to be held accountable for the work performed therein.

ABSTRACT

Occupancy models have become a valuable tool for estimating wildlife-habitat relationships and for predicting species distributions. Highly-mobile species often violate the assumption that sampling units are geographically closed shifting the probability of occupancy to be interpreted as the probability of use. We used occupancy models, in conjunction with noninvasive sampling, to estimate habitat use and predict the distribution of a highly-mobile carnivore, the American black bear (*Ursus americanus*) in New Mexico, USA. The top model indicated that black bears use areas with higher primary productivity and fewer roads. The predictive performance of such models is rarely validated with independent data, so we validated our model predictions with 2-independent datasets. We first assessed the correlation between predicted and observed habitat use for 28 telemetry-collared bears in the Jemez Mountains. Predicted habitat use was positively correlated with observed use for all 3 years (2012: $\rho = 0.81$; 2013: $\rho = 0.87$; 2014: $\rho = 0.90$). We then predicted the probability of use within a cell where a bear mortality was documented using 2043 mortality locations from sport harvest, depredation, and vehicle collisions. The probability of habitat use at a mortality location was also positively correlated with observed use by the species (2012: $\rho = 0.74$; 2013: $\rho = 0.89$; 2014: $\rho = 0.93$). Our validation procedure supports the notion that occupancy models can be an effective tool for estimating habitat use and predicting the distribution of highly-mobile species when the assumption of geographic closure has been violated. Our findings may be of interest to studies that are estimating habitat use for highly-mobile species that are secretive or rare, difficult to capture, or expensive to monitor with other more intensive methods.

1. Introduction

Since their inception, occupancy models have been an essential tool for the conservation and management of wildlife. In its original construction, the occupancy-modeling framework enabled estimation of the static occurrence and distribution of a single species while accounting for imperfect detection (MacKenzie et al., 2002). Recent extensions of the paradigm provide the ability to investigate the dynamic nature of various ecological processes that occur over time (MacKenzie et al., 2003) or among multiple species (MacKenzie et al., 2004) and include multiple occupancy states (Nichols et al., 2007). Generalizations of the model accommodate forms of heterogeneity and bias related to variation in abundance (Royle and Nichols, 2003), non-

independence among repeated surveys at sampling units (Nichols et al., 2008), and false-positives or misidentification of species (Miller et al., 2011) while investigating hierarchical scales of occurrence (Hines et al., 2010; Nichols et al., 2008). As a testament to their flexibility, occupancy models have helped explain the mechanisms driving the breeding dynamics of amphibians (Gould et al., 2019), have been used to monitor global-terrestrial biodiversity (Steenweg et al., 2017), have predicted future impacts of population growth and development on wildlife (Brown et al., 2014), and have been used to monitor the spread and dynamics of wildlife pathogens (Russell et al., 2017).

Occupancy models in their simplest form estimate the probability of occupancy (Ψ) in relation to habitat characteristics while accounting for imperfect detection by simultaneously estimating detection

probability (p) from repeated site visits (MacKenzie et al., 2002). When wildlife species violate the assumption that sampling units (e.g., a pond or a spatial sampling unit on the landscape) are closed to changes in occupancy state estimates of Ψ will be biased. However, if movements by a species in and out of sampling units are random, then Ψ can be interpreted as the probability a sampling unit is “used” rather than occupied and inferences about habitat use can be drawn (MacKenzie, 2006). Therefore, depending on whether closure can be assumed, occupancy modeling can be used to estimate the probability a species occurs at a site or the probability a species uses a site.

Highly-mobile species often violate the geographic closure assumption. Common sampling techniques used to collect presence-absence data for such species are often expensive and logistically challenging (e.g. telemetry collars and aerial surveys). Consequently, non-invasive sampling techniques for highly mobile species, such as camera and hair traps, have become more widely used. When noninvasive sampling techniques are coupled with occupancy modeling, a cost-effective approach arises for modeling habitat use and predicting a species' distribution that also embodies a sound statistical framework (MacKenzie et al., 2002).

For example, occupancy models have provided stakeholders with information on the predicted range of clouded leopards (*Neofelis nebulosa*) to help assess the efficacy of a conservation-corridor initiative on Peninsular Malaysia (Tan et al., 2017). They have also been used to model the effects of livestock grazing on large mammals determining that current laws are insufficient in safeguarding large mammal communities in protected reserves of the Hyrcanian forest of Iran (Soofi et al., 2018). Additionally, inferences from occupancy models have been used to develop maps of high-priority conservation areas helping inform local conservation organizations in their assessment and prioritization of land management and acquisition scenarios for forest-breeding birds in the United States (De Wan et al., 2009). Occupancy models have even been used to fight illegal activity detrimental to wildlife by providing a cost-effective method to predict and direct resources to combat poaching hotspots in Brazil (Ferreguetti et al., 2018).

Despite the common use of occupancy models, empirical studies have often failed to assess model fit and the predictive performance of the models. While some studies have examined violations in model assumptions, most studies did not identify the root cause of the violation (MacKenzie and Bailey, 2004; Royle et al., 2007; Warton et al., 2017). Furthermore, few empirical studies have used spatially-independent data to validate habitat use relationships (Babu et al., 2015; Drouilly et al., 2018; Zeller et al., 2011; but see Walpole et al., 2012). Failing to assess the fit and predictive performance of a habitat use model is particularly concerning given their importance in guiding conservation actions and wildlife policy decisions (Araújo et al., 2019; Guisan et al., 2013). Thus, the assumption that occupancy can be re-interpreted as habitat use when the assumption of geographic closure is not met for highly-mobile species has not been properly addressed.

The objective of our study was to use occupancy modeling coupled with noninvasive sampling to estimate habitat use for a highly-mobile species. We conducted a goodness-of-fit test to detect if violations of model assumptions had occurred and to evaluate the fit of the most supported model to the data. We then assessed the predictive performance of the most supported model at 2-different scales with 2-independent datasets. We show the efficacy of this approach using a case study on the American black bear (*Ursus americanus*) in New Mexico, USA.

2. Methods

2.1. Study area

We conducted our study in the Sangre de Cristo (9925 km²), Sacramento (3700 km²), and Jemez (~850 km²) Mountains, New Mexico, USA (Fig. 1). Elevation ranges from ~1500 m to 4011 m across

the 3 mountain ranges. Dominant vegetation types included subalpine coniferous forest (Engelmann spruce [*Picea engelmannii*], limber pine [*Pinus flexilis*] and subalpine fir [*Abies lasiocarpa*]), montane coniferous forest (Southwestern white pine [*P. strobiformes*], ponderosa pine [*P. ponderosa*], Douglas-fir [*Pseudotsuga menziesii*], white fir [*A. concolor*], blue spruce [*P. pungens*], and aspen [*Populus tremuloides*]), and coniferous and mixed woodland (piñon pine [*P. edulis*] and juniper [*Juniperus* spp.]; Dick-Pedie, 1993). Oak species (*Quercus* spp.) are scattered throughout mid- and low-elevation forests and are most abundant at lower elevations (Dick-Pedie, 1993). The average monthly temperature was highest in July and lowest in January ranging among the mountain ranges from 22 °C to 30 °C and –15 °C to –5 °C, respectively (Western Regional Climate Center, 2018). Average monthly precipitation varied among the mountain ranges from 7.10 cm to 12.70 cm and was highest during the monsoon season (Jul–Oct), with rainfall typically peaking in August (Western Regional Climate Center, 2018). In sum, the three mountain ranges were similar in orography, land cover, and climate.

2.2. Field sampling and genetic analysis

We used hair traps to sample black bears in the Sangre de Cristo and Sacramento mountains. Sampling within each study area was limited to primary habitat defined as all closed-canopy forest and woodland vegetation types (Costello et al., 2001). We distributed a grid of 5-km × 5-km cells with a randomly determined origin across the landscape. In each cell, we set a hair trap in a place most likely to encounter bears such as suspected travel routes, the occurrence of seasonal forage (e.g., green grass and ripe soft and hard mast), and the presence of bear sign (Kendall et al., 2009). Due to logistical constraints, a survey in the Sangre de Cristo Mountains lasted 4 weeks whereas a survey for the Sacramento Mountains was 2 weeks. We set hair traps across 4 surveys in the northern (22 Apr–5 Sep 2012) and southern Sangre de Cristo Mountains (29 Apr–9 Sep 2013) and across 6 surveys in the Sacramento Mountains (5 May–6 Aug 2014).

A hair trap consisted of a strand of barbed wire stretched 45 cm above ground and wrapped around ≥3 trees with a collection of organic material at the center (i.e., a lure pile). During each survey in the Sangre de Cristo Mountains, we randomly selected 1 of 4 non-consumable lures (cow blood/fish emulsion mixture [blood], skunk tincture/lanolin mixture [skunk], fatty acid scent tablet [FAS], or anise oil) and applied it to the lure pile. Based on this sampling, FAS and anise oil scent duration and dispersal distance appeared inferior to blood and skunk. A chi-square test of independence confirmed that the 4 lures were not collecting an equal number of samples ($\chi^2_3 = 616.29$, $P \leq 0.001$). In the Sacramento Mountains, we randomly selected and applied either blood or skunk lures to maximize detection of black bears. A sample consisted of all hair caught in one barb, and we used our best judgment to identify hair samples collected from when bears rolled around in the lure pile. We deposited each hair sample in a separate paper-coin envelope. Afterwards, we cleaned the barb wire with a propane torch to prevent false detections during subsequent surveys. We moved hair traps (100 m to 2.5 km) between surveys to help increase detection rates (Boulanger et al., 2006).

The only qualifier for an occupancy analysis is detection of the focal species (MacKenzie et al., 2002). We considered hair samples to be from a black bear if 2 odd numbered alleles were amplified for the G10J marker and if ≥4 loci were amplified across 8 additional genetic markers (G1D, G10B, G10L, G10M, G10H, G10J, G10U, MU59; Paetkau et al., 1998, 1995; Taberlet et al., 1997). The G10J marker is an indicator for black bears among North American ursids but has shown some cross-species amplification (L. Harris, Wildlife Genetics International, personal communication). All samples were exported to Wildlife Genetics International (WGI), Nelson, British Columbia, Canada under permits required by the Convention on International Trade in Endangered Species (Export Permits 12US86417A/9, 13US19950B/9, and 14US43944B/9).

(a) Location of our 3 study areas within New Mexico, USA overlaid on to a digital elevation map with hillshade where the color gradient from light to dark brown represents lower to higher elevations. (b) Telemetry locations of 1 American black bear (*Ursus americanus*) from 22 May 2013 to 31 August 2013 in the Jemez Mountains. Distribution of hair traps in the (c) Sangre de Cristo, 2012–2013 and (d) Sacramento Mountains, 2014. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Kindschuh et al. (2016) captured adult-black bears in the Jemez Mountains from June 2012–July 2014 using culvert traps and foot snares. They fitted individuals with a global positioning system (GPS) telemetry collar programmed with a 3 h fix interval (Advanced Telemetry Systems model G2110E, Isanti, Minnesota, USA or Northstar model NSG-LD2, King George, Virginia, USA). Our sampling procedures were approved by the New Mexico State University Institutional Animal Care and Use Committee (Protocols #2011-027) and New Mexico Department of Game and Fish (Scientific Collection Permit 3504). The New Mexico Department of Game and Fish (NMDGF) provided locations on statewide sport-hunted, depredation, and vehicle collision mortalities collected in 2012–2014.

2.3. Modeling habitat use

We used single-species, single-season occupancy models to investigate habitat use by black bears (MacKenzie et al., 2002). We used the results from our genetic analysis to create a detection history for each 5-km × 5-km cell. While habitat use was the primary objective of our occupancy modeling analysis, providing an accurate depiction of the detection process to eliminate negative bias is essential to the overall model fit and an accurate depiction of habitat use (MacKenzie et al., 2002). We hypothesized that detection may be influenced by the distance of a hair trap to a road (dist), lure scent (lure), and mountain range (mtn) with mtn depicting the natural variation in the movement

behavior of bears from different mountain ranges or due to differences in survey length between the Sangre de Cristo and Sacramento mountains. We predicted a lower detection probability when we set hair traps closer to roads as bears have been shown to avoid roads (Simek et al., 2015; Stillfried et al., 2015). We predicted a higher detection probability when we used blood as a lure based on the results of our chi-square test of independence. We also predicted a higher detection probability in the Sangre de Cristo Mountains because the length of the surveys was longer. We pooled the detection data by survey across the 2 mountain ranges. This resulted in the detection history having 6 total surveys with sites in the Sangre de Cristo Mountains censored in surveys 5 and 6. Due to their ineffectiveness in the Sangre de Cristo Mountains, we pooled the anise oil and FAS lures into 1 lure category.

We modeled habitat use by developing a suite of a priori models. We hypothesized that habitat use would be influenced by: 1) spatio-temporal variation in primary productivity because food availability influences reproduction and survival (Costello et al., 2003), 2) terrain complexity because it reflects hydrological profiles that may influence security cover, forage diversity, and primary productivity (Berryman et al., 2015), and 3) road density because of increased human disturbance and perceived risk and reduced survival (Hostetler et al., 2009). We selected the enhanced vegetation index (EVI), its coefficient of variation (EVICV), and dominant land cover type (cover) as covariates correlated with food availability (Merkle et al., 2013; Nijland et al., 2016). We predicted higher use in cells with a higher mean EVI (a measure of productivity) and mean EVICV (a measure of seasonality; Requeña-Mullor et al., 2014). We predicted a positive relationship with seasonality because pulses of productivity that occurred predominantly during the summer would be more advantageous for bears as they prepare for hibernation (Wiegand et al., 2008). The EVI has been shown to be sensitive to spatial and temporal variation in photosynthetic activity and has improved corrections for aerosols and cloud cover compared to NDVI (Huete et al., 2002). We predicted higher use of mixed conifer and spruce-fir land cover, which tend to occur at mid- to high-elevations, because these classifications likely represent early-seasonal grasses and soft-mast plant communities that contain important black bear food during the period that our study was conducted (Guntly, 2016). We predicted a positive association with the terrain ruggedness index (TRI) because greater terrain complexity would result in more diverse hydrological profiles that should yield higher forage diversity and primary productivity (Berryman et al., 2015; Nellemann et al., 2007). We predicted that a higher density of roads open to mechanized travel would be used less due to increased anthropogenic disturbance (Gaines et al., 2005; Hostetler et al., 2009). Last, we assigned mtn as a group variable to evaluate if habitat use was specific to or similar across mountain ranges.

We calculated EVI using 16-day, 250 m Moderate Resolution Imaging Spectrometer (MODIS) datasets (Huete et al., 2002). We generated a single EVI and EVICV value for each cell by averaging all 250 m pixels within a 5-km × 5-km cell for each MODIS image and then averaging all MODIS images across all surveys. We reclassified the 30 m LANDFIRE land cover data into 5 classes that represented black bear habitat: mixed conifer (combination of aspen, Douglas fir, white pine), piñon pine-juniper, ponderosa pine, spruce-fir, and all remaining classes (www.landfire.gov; Rollins, 2009). We assigned a sixth classification of “heterogeneous” when no classification represented ≥50% of the area within the cell. We calculated TRI using a National Elevation Dataset 30 m digital elevation model (www.nationalmap.gov) and the Benthic Terrain Modeler in ArcMap. We generated a single, averaged TRI value for each cell. We measured road density and distance to roads using the U.S. Census Bureau's 2010 TIGER/Line county-road dataset (www.rgis.unm.edu). We extracted all model covariates using ArcMap 10.2.1 (Environmental Systems Research Institute, Inc., Redlands, California, USA).

We used a multi-step modeling process to determine the final model structure for p and Ψ (Doherty et al., 2012). First, we standardized all

continuous covariates by subtracting the mean and dividing by 2 standard deviations (Gelman, 2008). We assessed multicollinearity between continuous covariates by calculating Pearson's sample correlation (r) between all covariate combinations, with $r \geq 0.60$ disqualifying use of a covariate combination in a model. We used box plots to visually evaluate trends between the categorical land cover variable and each continuous covariate. Land cover and EVI were correlated, so we did not include them in the same model. We first modeled p by dist, lure, mtn, all additive combinations of the 3 covariates, or constant while using the global model for Ψ . We then incorporated the model structure from the top model for p into our subsequent modeling of Ψ using all additive combinations of the uncorrelated covariates except for EVICV, which was only included in models with EVI. We also included an interaction between TRI and EVI as we hypothesized cells with high EVI and low TRI may be used less by bears because the cell may be more accessible to human activity or contains more open fields than forest cover.

We used Akaike's Information Criterion corrected for small sample size (AICc; Hurvich and Tsai, 1989) to rank and determine relative support among models. We used the AICc weights (w_i) to assess proportional support for each model (Burnham and Anderson, 2002). We assessed the goodness-of-fit for the top-ranked model using visual diagnostic plots based on simulated Dunn-Smyth residuals for occupancy following methods in Warton et al. (2017). If the 95% confidence interval (CI) of the simulation overlapped 0, then we assumed the model fit the data and that there were no violations of model assumptions. We performed our occupancy analysis and model ranking using program MARK (White and Burnham, 1999). All other analyses were performed in program R (v. 3.4.4 and v. 3.5.1; R Core Team, 2017, 2018).

2.4. Validating the habitat use model

We used the parameter structure for Ψ from the top model to predict the distribution of black bears at 2-spatial scales, the Jemez Mountains and New Mexico state. We limited predicted habitat use in the Jemez Mountains to primary habitat to evaluate how well the top model predicted habitat use in a mountain range that is similar in habitat but independent of the Sangre de Cristo and Sacramento mountains (Costello et al., 2001). We did not limit predicted habitat use for New Mexico to primary habitat to evaluate how well the model performed outside of the conditions used to construct it. We validated these maps by comparing predicted to observed habitat use based on GPS and mortality locations for each respective scale. We selected GPS locations that were collected during the same time that hair samples were collected in the Sangre de Cristo and Sacramento mountains, whereas, we used all mortality locations collected in 2012–2014.

First, from a random starting location, we overlaid a grid of 5-km × 5-km cells over primary bear habitat within the Jemez Mountains and across all of New Mexico. We then predicted the probability of use for each cell. We scaled the predicted probabilities of the cells to sum to 1, grouped them into 20-equally sized bins, and then summed within each bin:

$$P(USE) = \sum_j \hat{\Psi}_{ij}$$

where i is the bin identifier, j is the grid cell, and $\hat{\Psi}$ is the probability of habitat use for 1 to N grid cells (Boyce et al., 2002; Howlin et al., 2004). Next, we summed the proportion of observed habitat use for each grid cell by bin:

$$O(USE) = \sum_j \frac{r_{ij}}{r}$$

where i is the bin identifier, j is the grid cell, and r is the observed collar and mortality locations in the study area (Boyce et al., 2002; Howlin et al., 2004). We then conducted a Spearman's rank correlation test to

assess the correlation between predicted and observed habitat use and assumed predicted and observed use would be positively correlated ($\rho \geq 0.60$; Boyce et al., 2002). We also generated a histogram that described the distribution of mortality locations across the distribution of predicted use probabilities for New Mexico. We assumed that each source of mortality was proportional to use, and locations would be found in cells with a higher probability of use. If not, the habitat use model was not a good predictor of habitat use across New Mexico, or the source of mortality may have biased locations towards low-quality habitat due to higher road densities resulting in greater hunter access (sport-harvest), greater anthropogenic attractants (depredation), or higher road densities in areas outside of non-primary habitat (vehicle collision).

3. Results

3.1. Field sampling and genetic analysis

We set 397 and 148 hair traps that were open for 43,951 and 12,080 trap days in the Sangre de Cristo and Sacramento mountains, respectively. These traps collected 2485 and 1198 hair samples with 60% and 53% of hair traps collecting ≥ 1 black bear hair sample. We obtained DNA suitable for amplification from 1813 and 851 hair samples, and we identified 1046 and 546 samples as black bear in the Sangre de Cristo and Sacramento mountains, respectively. In the Jemez Mountains, Kindschuh et al. (2016) live-captured 28 individual bears (19 male; 9 female) from which the telemetry collars obtained 30,660 (22,429 male; 8231 female) GPS locations that coincided with sampling periods in the Sangre de Cristo and Sacramento mountains. New Mexico Department of Game and Fish collected 711, 776, and 556 mortality locations during a 3-yr period (2012–2014), respectively.

3.2. Modeling habitat use

The top-ranked detection model included lure and mtn as covariates and was supported almost twice as much ($w_i = 0.61$) as the second ranked model ($w_i = 0.32$; Appendix Table A.1). The second ranked model differed from the top model by only 1 parameter and both had nearly identical deviances. The additional covariate in the second-ranked model (dist) was uninformative and the competitiveness of the two models was a consequence of a model structure that was similar to the top-ranked model (Arnold, 2010). Therefore, we used the model structure from the top-ranked model for our subsequent modeling of Ψ . As we predicted, detection probability was highest for the blood lure and in the Sangre de Cristo Mountains (Fig. 2). The 95% CIs for the beta coefficients did not overlap 0 for all detection probability covariates (blood: $\beta = 1.28$, 95% CI = 0.99–1.58; skunk: $\beta = 0.73$, 95% CI = 0.43–1.02; mtn: $\beta = 0.39$, 95% CI = 0.11–0.66). The ratio between standardized beta coefficients showed blood had the largest effect relative to skunk (1.76) and mtn (3.33) and skunk had a larger effect than mtn (1.89).

The hypotheses that primary productivity and road density affect black bear habitat use were supported. The top-ranked model for Ψ included EVI, EVICV, and road density, however, this model received just over a third of the total model weight ($w_i = 0.36$). The second and third ranked models differed from the top model by only 1 parameter and had nearly identical deviances as the top model. Like the results for modeling p , the competitiveness of the 2 models was a consequence of a model structure that was similar to the top-ranked model. Thus, we eliminated the 2 models with the uninformative covariates (TRI and mtn) from our model set and the w_i for the top-ranked model increased to 0.52 (Appendix Table A.2). The next 11 models contained a cumulative weight of 0.45 and all but 2 had EVI as a covariate. Consistent with our predictions, habitat use increased with increasing EVI and EVICV and decreased with increasing road density (Fig. 2). The 95% CIs for the beta coefficients did not overlap 0 for all probability of use

covariates (EVI: $\beta = 2.66$, 95% CI = 1.90–3.42; EVICV: $\beta = 0.84$, 95% CI = 0.20–1.47; road: $\beta = -0.53$, 95% CI = -1.02 to -0.05). The ratio between standardized beta coefficients showed that EVI had the largest effect on probability of use relative to EVICV (3.18) and road density (4.97) and EVICV had a larger effect than road density (1.56). The visual diagnostic plots did not show a lack-of-fit for the top model as the 95% CIs for all simulations overlapped 0 (Appendix Figs. B.1 and B.2). The observed proportion of cells used across both mountain ranges was 0.58 and when corrected for imperfect detection, the estimated probability of cell use was $\hat{\Psi} = 0.74$ (SE = 0.03).

3.3. Validating the habitat use model

We used the model structure for Ψ from the top-ranked occupancy model to predict habitat use for bears in the Jemez Mountains and New Mexico because it received $5\times$ more support than the second-ranked model and because nearly all of the remaining models contained EVI (Appendix Table A.2). Predicted habitat use was positively correlated with observed use for all 3 years in the Jemez Mountains (2012: $\rho = 0.81$; 2013: $\rho = 0.87$; 2014: $\rho = 0.90$) and across New Mexico (2012: $\rho = 0.74$; 2013: $\rho = 0.89$; 2014: $\rho = 0.93$). Eighty-two percent, 72%, and 77% of all mortality locations in 2012–2014, respectively, fell within cells that had a predicted probability of habitat use of ≥ 0.90 even though these cells represented only 18–19% of the total cells in New Mexico during the 3 years (Fig. 3; Appendix Fig. C.1). When separated by cause-specific mortality cells that had a predicted probability of habitat use of ≥ 0.90 contained the highest number of mortalities (sport-hunted: 82–87%; depredation: 50–67%; vehicle collision: 37–50%; Appendix Fig. C.1).

4. Discussion

4.1. Benefits of occupancy modeling

Occupancy modeling is a flexible and reliable statistical method that separates the observation process from the ecological process (i.e., p and Ψ) and yields a more accurate representation of where a species has been detected and how it uses the landscape (Kéry et al., 2013; Lahoz-Monfort et al., 2014). This level of inference is valuable because environmental characteristics can affect the detection of a species and bias descriptions of habitat use leading to ill-informed conservation and management plans (MacKenzie, 2006). Our research highlights the utility of occupancy modeling, coupled with noninvasive sampling, to estimate habitat use for highly-mobile species. A unique aspect of our study was the opportunity to use independent data to assess the predictive performance of our model. Our empirical validation procedure reinforces the view that occupancy modeling can be used to estimate habitat use when the assumption that geographic closure of sampling units is violated by a highly-mobile species.

Additionally, when paired with thoughtful and flexible study designs occupancy models can help achieve multiple research objectives. For example, Gould et al. (2018) used noninvasive genetic sampling to estimate the density of black bears, and then we used these data to explore habitat use over large-spatial scale that would have been too financially exorbitant with telemetry collars. In studies that use camera traps, researchers could use occupancy modeling to simultaneously analyze range and community dynamics, investigate species interactions, and monitor biodiversity (Kéry et al., 2013; Rich et al., 2017; Robinson et al., 2014). Occupancy modeling, however, may not always be the most appropriate method for a study. For instance, research on cause-specific mortality, foraging behavior, and 2nd–4th order resource selection requires detailed spatiotemporal location data necessitating the use of telemetry collars (Manly et al., 2002). Despite its strengths, the decision to use occupancy modeling will depend on the ecological questions of interest and monetary constraints of a project.

Fig. 2. (a) The probability of detection as a function of lure type (blood, skunk, fatty acid scent tablet [FAS] and anise oil) and mountain range (Sangre de Cristo Mountains = filled circles, Sacramento Mountains = unfilled circles) and (b) the probability of habitat use (Ψ) with respect to the enhanced vegetation index (EVI), (c) its coefficient of variation (EVICV), and (d) road density. Gray shade represents the 95% confidence intervals of the probability of habitat use.

4.2. Validating the habitat use model

Our predicted species distribution maps for black bears exhibited high spatiotemporal concordance with observed habitat use at both spatial scales. Model predictions are often not validated or are validated without using independent data because these data are often difficult and costly to obtain. Instead, researchers typically split the occurrence data into training and testing datasets. They then use the training dataset to generate a single habitat use model, or iteratively generate multiple habitat use models, and validate the model(s) using the testing dataset (e.g., k-fold cross-validation; Boyce et al., 2002). A more informative approach would be to estimate habitat use using the full dataset ensuring a larger sample and greater statistical power to describe patterns of habitat use. Then validate the predictive performance of the model using independent data. Yet, researchers rarely have access to additional independent data, whereas, we were fortunate to have 2-independent datasets available to evaluate our habitat use model.

In the United States, state wildlife management agencies commonly collect mortality information on multiple species so such data are often available to serve as independent data sets. Mortality locations, however, can be biased depending on the cause of mortality. For example, sport harvest locations may be biased due to hunter selectivity and the accessibility of an area to motorized vehicles. Depredation mortalities may be biased if artificial attractants occur outside of high-use habitat. While vehicle collisions may be biased dependent on road type (e.g., interstate vs. dirt). All mortality sources will likely be affected by differential movements of the species due to sex and age (e.g., dispersing juveniles) and increased and uncommon movement patterns due to drought-induced failure of food crops (Costello, 2010; Jones et al., 2015; Kerley et al., 2002). The mortality data we used was male-biased as more males were either killed by sport harvest (1.5–1.6 males:1.0 female), removed because of depredation events (2.0–4.0 males:1.0 female), or killed by vehicle collisions (1.1–2.0 males:1.0 female) across the 3 years. The larger proportion of males is likely a combination of male biased harvest limits, larger movement rates relative to females, and female-biased philopatry, which could increase a male's risk of mortality due to increased interaction with roads and humans (Lee and Vaughan, 2003; Costello, 2010; Gould et al., 2018). Despite these

concerns, it seems logical that bears would use areas that are either easier to travel through, to conserve energy, or contain the resources they need to meet their energy requirements. Our assumption seems reasonable, given most of the cause-specific mortality locations were found in areas with a predicted probability of use ≥ 0.90 (Appendix Fig. C.1).

4.3. Modeling habitat use

The simulated Dunn-Smyth residuals for occupancy did not show any pattern and the 95% CIs for all simulations overlapped 0 suggesting that the model fit the data well and that the assumptions of the model were not violated (Appendix Figs. B.1 and B.2). The model assumption of geographic closure, however, was indeed violated due to the extended sampling period (Gould et al., 2018). Instead, these results likely indicate that movement in and out of the sampling units by the species was random and the probability of occupancy could be interpreted as use.

Habitat use by black bears in New Mexico had a positive relationship with primary productivity and its variation, which likely describes the spatiotemporal distribution of food resources. This relationship can be explained by their omnivorous diet, which is comprised predominantly of vegetative matter (Costello et al., 2001; McLellan, 2011). The positive relationships between primary productivity and habitat use is consistent with various ursid studies that have shown a correlation between primary productivity and population-level habitat selection, habitat quality, and patterns in density (Duquette et al., 2017; Stetz et al., 2018; Wiegand et al., 2008).

Incorporating variables on ecosystem functions (i.e., covariates representing multiple rather than a single ecosystem process) into modeling habitat use has become increasingly popular because they more realistically track ecological patterns (Cabello et al., 2012). Ecosystem functioning variables have improved predictions by species distribution models (Requena-Mullor et al., 2014) and have helped explain diet patterns, population cycles, and habitat use in several mammalian species (Schmidt et al., 2018; Squires et al., 2013; Tsuji et al., 2015). We used EVI and EVICV to represent primary productivity and seasonality, respectively. Land cover combined with road density, however, had a similar performance as the top model as the 2 had nearly identical

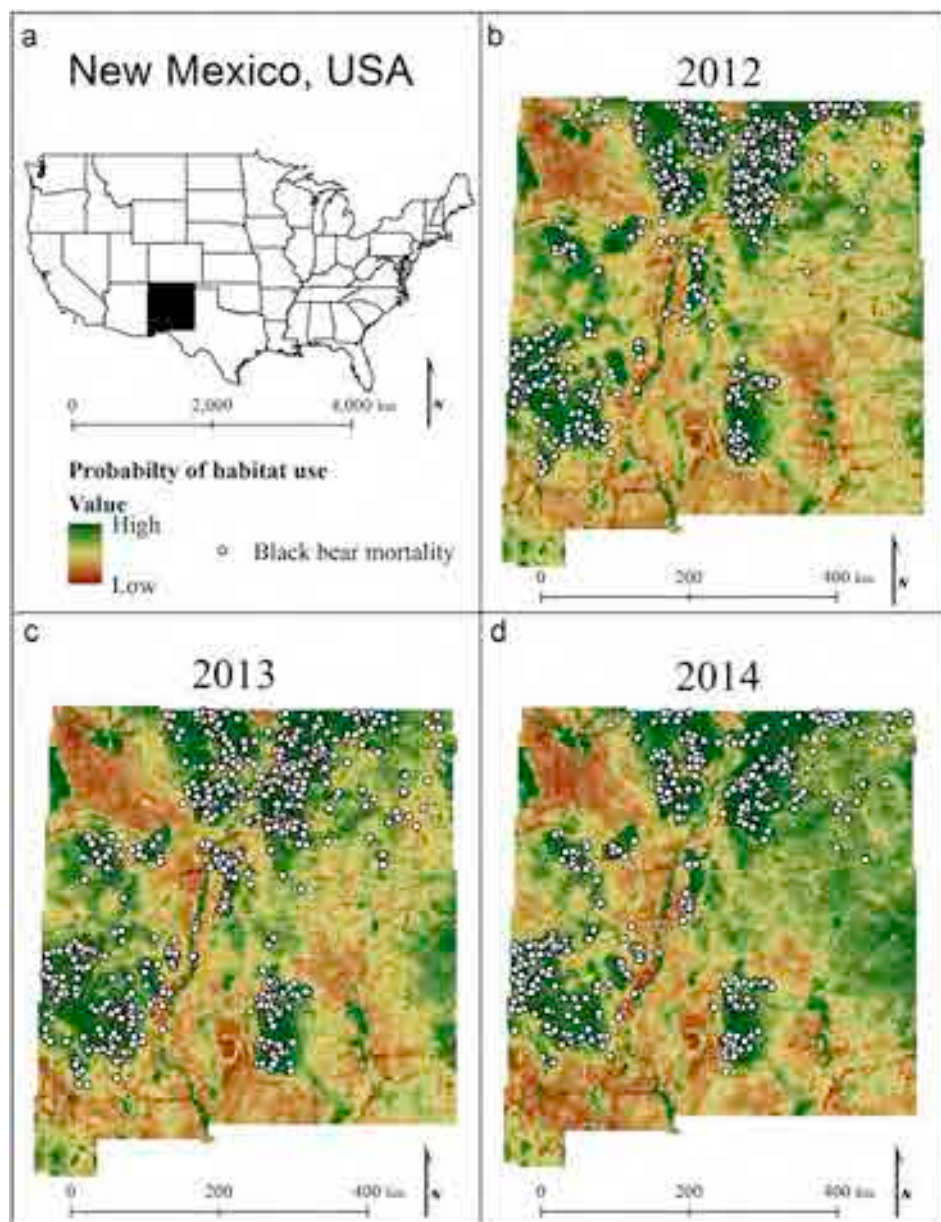

Fig. 3. The predicted probability of habitat use for American black bears (*Ursus americanus*) across (a) New Mexico, USA overlaid with black bear mortality locations in (b) 2012, (c) 2013, and (d) 2014.

deviance values. The similarity in performance most likely arose because EVI and land cover were correlated, but land cover was not ranked highly due to parsimony (Burnham and Anderson, 2002). Thus, land cover may be a good predictor of bear habitat use, but ecosystem functioning variables are more advantageous because they can often be assessed with a single, continuous variable resulting in 2 parameters (intercept and slope) and can characterize the dynamic, spatiotemporal heterogeneity in ecosystem processes more efficiently than a categorical land cover variable. The occupancy model, however, over-predicted habitat use in east-central New Mexico along the Texas border. The EVI and EVICV were likely sensitive to agriculture-based irrigation and the presence of shinners oak (*Quercus havardii*), a deciduous and low-growing shrub. Therefore, some subjectivity based on biological expertise may be necessary when constructing and interpreting habitat use models that are extrapolated outside the area they were generated.

Our results also suggest that habitat use is influenced by road density, but to a much lesser degree than primary productivity. The

negative relationship between road density and habitat use is consistent with a large body of research that has highlighted the negative impact of roads on ursids, including increasing habitat loss, reducing habitat quality, heightening genetic isolation, and increasing mortality rates (Dixon et al., 2007; Little et al., 2017). Roads are also negatively correlated with habitat use of other mammals, from marsupials to small rodents and large-obligate carnivores with greater impacts on species exhibiting low reproduction and high vagility (i.e., highly-mobile species; Kerley et al., 2002; McAlpine et al., 2006; Kelly et al., 2013; Rytwinski and Fahrig, 2011).

We found no support that habitat use was related to terrain complexity or differences between mountain ranges (Appendix Table A.2). Terrain complexity may not have been supported because the scale of our study and the sample of available units was limited to mountain ranges. If we had broadened the geographic scale of sampling for the development of our occupancy model, a greater proportion of less rugged areas would have been included and terrain complexity likely would have been an important predictor of broad-scale habitat use for black bears.

4.4. Conclusions

Predictive maps highlighting wildlife-habitat use and predicting a species' distribution can be valuable tools for developing a better understanding of a species' spatial ecology, thereby informing species management and conservation plans. Occupancy models provide practitioners with the ability to estimate and predict these relationships while accounting for imperfect detection of a species. Using 2-validation datasets, we assessed the performance of occupancy models for estimating habitat use and predicting the distribution of a highly-mobile species, the American black bear. Despite our predictions occurring in an independent mountain range and outside of the habitat conditions upon which the model was constructed, predicted and observed habitat use were positively correlated. Our validation procedure supports the notion that occupancy models can be an effective tool for estimating habitat use and predicting the distribution of highly-mobile species when the assumption of geographic closure has been violated. Our findings may be particularly useful when conservation and management agencies are charged with estimating habitat use for highly-mobile species that are secretive or rare, difficult to capture, or expensive to monitor with other more intensive methods.

Abstract

The phylogeography of the American black bear (*Ursus americanus*) is characterized by isolation into glacial refugia, followed by population expansion and genetic admixture. Anthropogenic activities, including overharvest, habitat loss, and transportation infrastructure, have also influenced their landscape genetic structure. We describe the genetic structure of the American black bear in the American Southwest and northern Mexico and investigate how prehistoric and contemporary forces shaped genetic structure and influenced gene flow. Using a suite of microsatellites and a sample of 550 bears, we identified 14 subpopulations organized hierarchically following the distribution of ecoregions and mountain ranges containing black bear habitat. The pattern of subdivision we observed is more likely a product of postglacial habitat fragmentation during the Pleistocene and Holocene, rather than a consequence of contemporary anthropogenic barriers to movement during the Anthropocene. We used linear mixed-effects models to quantify the relationship between landscape resistance and genetic distance among individuals, which indicated that both isolation by resistance and geographic distance govern gene flow. Gene flow was highest among subpopulations occupying large tracts of contiguous habitat, was reduced among subpopulations in the Madrean Sky Island Archipelago, where montane habitat exists within a lowland matrix of arid lands, and was essentially nonexistent between two isolated subpopulations. We found significant asymmetric gene flow supporting the hypothesis that bears expanded northward from a Pleistocene refugium located in the American Southwest and northern Mexico and that major highways were not yet affecting gene flow. The potential vulnerability of the species to climate change, transportation infrastructure, and the US–Mexico border wall highlights conservation challenges and opportunities for binational collaboration.

1 | INTRODUCTION

The Pleistocene epoch (2.6–0.012 mya) represents a geologic period characterized by massive climatic fluctuations that drove dynamic glacial–interglacial cycles with profound effects on the global distribution and genetic structure of flora and fauna (Hofreiter & Stewart, 2009). Glacial advance contracted species' ranges into refugial pockets of habitat where isolation, selection, and genetic drift resulted in genetic differentiation among populations. Upon glacial recession, species expanded out of their respective refugia into their current distribution resulting in latitudinal patterns of species assemblages, genetic structure, and areas of admixture between formerly isolated populations (Lomolino et al., 1989; Puckett et al., 2015; Shafer et al., 2010). The phylogeographic influence of these glacial–interglacial dynamics has been observed for vagile species like the gray wolf (*Canis lupus*; Weckworth et al., 2010) and red fox (*Vulpes vulpes*; Aubry et al., 2009) and for more habitat-restricted species like the woodland caribou (*Rangifer tarandus caribou*; Klütsch et al., 2012) and American marten (*Martes americana*; Stone et al., 2002). The location of refugia is highly dependent on the life history of the organism.

The American black bear (*Ursus americanus*; hereafter, black bear) is a large omnivore endemic to the forests of North America. Its distribution and genetic structure have been an ebb and flow of isolation and admixture events dictated by glacial tides of the Pleistocene (Puckett et al., 2015). Mitochondrial and nuclear data indicate that black bears were last isolated during the Last Glacial Maximum (LGM) ~26.5 kya and had contracted into three glacial refugia located in Beringia, the Pacific Northwest, and the American Southeast, and a fourth hypothesized refugium in the southwestern United States and northern Mexico (hereafter, the Southwest; Puckett et al., 2015; Varas-Nelson, 2010). As glaciers receded (~20 kya), black bears expanded out of their respective refugia resulting in admixture among populations in west-central and east-central North America and the formation of region-specific subpopulations (Pelletier et al., 2011; Puckett et al., 2015). Black bears across their northern range are genetically diverse and inhabit a large, contiguous landscape with a genetic structure that is consistent with isolation by distance due to female-biased philopatry (Pelletier et al., 2011; Pelletier et al., 2017). Despite support for a fourth glacial refugium in the Southwest (Puckett et al., 2015; Varas-Nelson, 2010), there remains some uncertainty as these inferences are based on limited geographic sampling, particularly in the southeast portion of New Mexico (Onorato et al., 2007; Onorato, Hellgren, Van Den Bussche, & Doan-Crider, 2004). Furthermore, conflicting inferences regarding

the genetic structure of black bears have been made in Arizona and New Mexico, where bear populations have been reported as both genetically structured and admixed (Atwood et al., 2011; Varas-Nelson, 2010; Winslow, 2012).

The potential existence of a southwestern refugium for black bears is independently supported by paleoecological reconstruction of woodrat (*Neotoma* spp.) paleomiddens (Betancourt et al., 1990). Woodrats collect plant material and pollen blows in or adheres to plants and the macrofossils and pollen become encased in crystallized woodrat urine, or amberat, that form an indurated paleomidden (Spaulding et al., 1990). Investigations of these paleomiddens reveal information about the relative abundance, distribution, and species composition of prehistoric plant communities, which in turn enable assessments of climatic and plant community change (Betancourt et al., 1990). These investigations indicate that during the late Pleistocene and early Holocene (12 kya–present), areas within what are now the Chihuahuan and Sonoran deserts of the southwestern United States and northern Mexico, contained large areas dominated by pygmy conifer forest, a plant community comprising important food plants of black bears, including those that produce hard mast such as piñon pine (*Pinus* spp.), juniper (*Juniperus* spp.), and oak (*Quercus* spp.; Betancourt et al., 1990, Chp. 21; Holmgren et al., 2006; McAuliffe & Van Devender, 1998; Onorato et al., 2003). Conversely, areas farther north, in northern Arizona and New Mexico and southern Colorado and Utah, contained less hospitable habitat including montane glaciers, tundra, and taiga as well as forests dominated by yellow pine (*Pinus* spp.), limber pine (*P. flexilis*), and lodgepole pine (*P. contorta*). These regions currently harbor more contiguous black bear habitat. As the Holocene aridified, habitats preferred by bears either shifted up in elevation, such as in the Madrean Sky Islands along the US–Mexico border, or farther north in latitude and the bears likely followed suit. Thus, vicariant events, namely climatic change that drove the distribution of important food plants for this forest-adapted species, may have influenced the distribution of black bears. This pattern of vicariance and migration may be visible in the genetic structure of contemporary black bear populations.

Anthropogenic activities, in particular, overharvest, urbanization, and transportation infrastructure such as highways with high traffic volume have also influenced the abundance, movement patterns, and genetic structure of black bears. In the western and eastern portions of their range, overhunting and persecution during European settlement severely reduced the abundance of black bears with some populations recovering and recolonizing portions of their former range (Evans et al., 2017; Malaney et al., 2018), while others

have been rendered into small, isolated populations more susceptible to genetic drift, eroding genetic diversity (Hooker et al., 2015; Murphy et al., 2017; Murphy et al., 2018). In Florida, major roads have heightened mortality (McCown et al., 2009) and acted as semipermeable barriers, that when coupled with urbanization, fragmented bear habitat, decreased connectivity, and caused appreciable genetic structure among subpopulations (Dixon et al., 2007; Karelus et al., 2017). In the Lower Mississippi Alluvial Valley of Louisiana, human-caused mortality combined with extensive habitat loss and fragmentation forced black bears into a patchwork of small populations isolated by anthropogenic activities; active translocations are underway to help restore bear populations there (Murphy et al., 2018). In several states, roads have been shown to influence movements and patterns of habitat selection, as bears either avoid roads or select areas farther from roads, and in some regions, roads created genetic substructure by acting as filters to bear movement (Cushman & Lewis, 2010; Dixon et al., 2007; Gould et al., 2019; Hiller et al., 2015; Short Bull et al., 2011).

In the Southwest, limited geographic and genetic sampling has obscured the influence of prehistoric and contemporary ecological processes that shape genetic structure and govern gene flow of black bear populations. Our aim was to fill a crucial gap regarding the large-scale population genetic structure of the American black bear by using a suite of microsatellite loci to characterize the genetic profile of 550 individual bears sampled across the Southwest. We focused on two hypotheses. First, we hypothesized that the current genetic structure could be a consequence of Pleistocene–Holocene vicariance whereby bears occupied forest refugia during the LGM, but then followed changes in the distribution of forests as the Holocene dried and warmed (Pleistocene–Holocene Vicariance Hypothesis). If true, we predicted that bears occupying contiguous forests should be relatively closely related and exhibit little genetic substructure. Bears in the Madrean Sky Islands should be more genetically structured (Atwood et al., 2011; Varas-Nelson, 2010) and should show evidence of gene flow characterized by isolation by resistance. Finally, there should be a pronounced asymmetric pattern of gene flow from south to north. Second, we hypothesized that the genetic substructure of bears could be dominated by anthropogenic activities typifying the Anthropocene (i.e., the concept that we are living in a time when human activities have significant effects on the global environment). If true, we predicted that the influence of major highways would be manifested by bears being more closely related on the same side of a highway and more distantly related on opposite sides. This should occur irrespective of the intervening habitat matrix. Although highways may not be barriers, they should act as semipermeable filters that influence gene flow (Anthropocene Filter Hypothesis). Expectations from these hypotheses may not be mutually exclusive, but we envision that the strength of evidence gathered through our analysis will expose their relative importance and that the insight gained will illuminate the processes that helped shape the phylogeography and present-day genetic structure of black bears in the Southwest. Our findings will also aid in the conservation and management of black bears by identifying genetically

isolated populations and the landscape features promoting or inhibiting genetic connectivity among black bear populations.

2 | MATERIALS AND METHODS

2.1 | Study area

We conducted our study in the southwestern United States (Arizona, Colorado, New Mexico, Texas, and Utah) and northern Coahuila de Zaragoza, Mexico (Figure 1). Orography and climate vary drastically throughout the Southwest with elevation ranging from 21 m at the southwest corner of Arizona to 4155 m-high peaks in southern Colorado. The desert and grassland communities receive the majority of the ~100–300 mm of annual precipitation during the July to October monsoon season with mean monthly maximum temperatures for July from 1961 to 1990 ranging from ~16 to 40°C (Davey et al., 2006, 2007a, 2007b). The forest communities receive the majority of the ~300 to 1250 mm of annual precipitation during the winter with mean monthly minimum temperature for January from 1961 to 1990 ranging from ~−20 to −4°C (Davey et al., 2006, 2007a, 2007b).

Black bears in the Southwest inhabit a mosaic of habitat distributed throughout three ecoregions: Northwestern Forested Mountains, Temperate Sierras, and Southern Semiarid Highlands which themselves are often separated by the North American Deserts ecoregion (Omernik & Griffith, 2014). Biotic communities at higher elevations and latitudes consist of Petran Subalpine and Petran Montane conifer forests transitioning to mid-elevation Great Basin Conifer and Madrean Evergreen woodlands (Brown, 1994). Large expanses of low-elevation valleys are composed of biotic communities such as Plains and Great Basin Grassland, Semidesert Grassland, and the Great Basin, Chihuahuan, and Sonoran desert scrub. These areas comprise a low elevation “sea” that is not typically used by black bears, isolating them on montane ‘sky islands’ (Brown, 1994; Hellgren et al., 2005; Olson et al., 2001).

2.2 | Sample and marker selection

We collected genetic samples from individual black bears through hunter harvest, live-capture, noninvasive genetic sampling, and vehicle collisions. We attempted to sample ≥25 individuals from each mountain range to obtain an adequate representation of allele frequency and diversity within each assumed subpopulation (Hale et al., 2012). Despite there being evidence that bears from west Texas and northern Coahuila de Zaragoza, Mexico, have genetic signatures more similar to bears in the southeast United States (Onorato et al., 2007; Onorato, Hellgren, Van Den Bussche, & Doan-Crider, 2004; Pedersen et al., 2021, Van Den Bussche et al., 2009), we included individuals from this region in our analysis because limited geographic sampling of black bears in New Mexico creates the possibility of a link between west Texas and northern Coahuila de

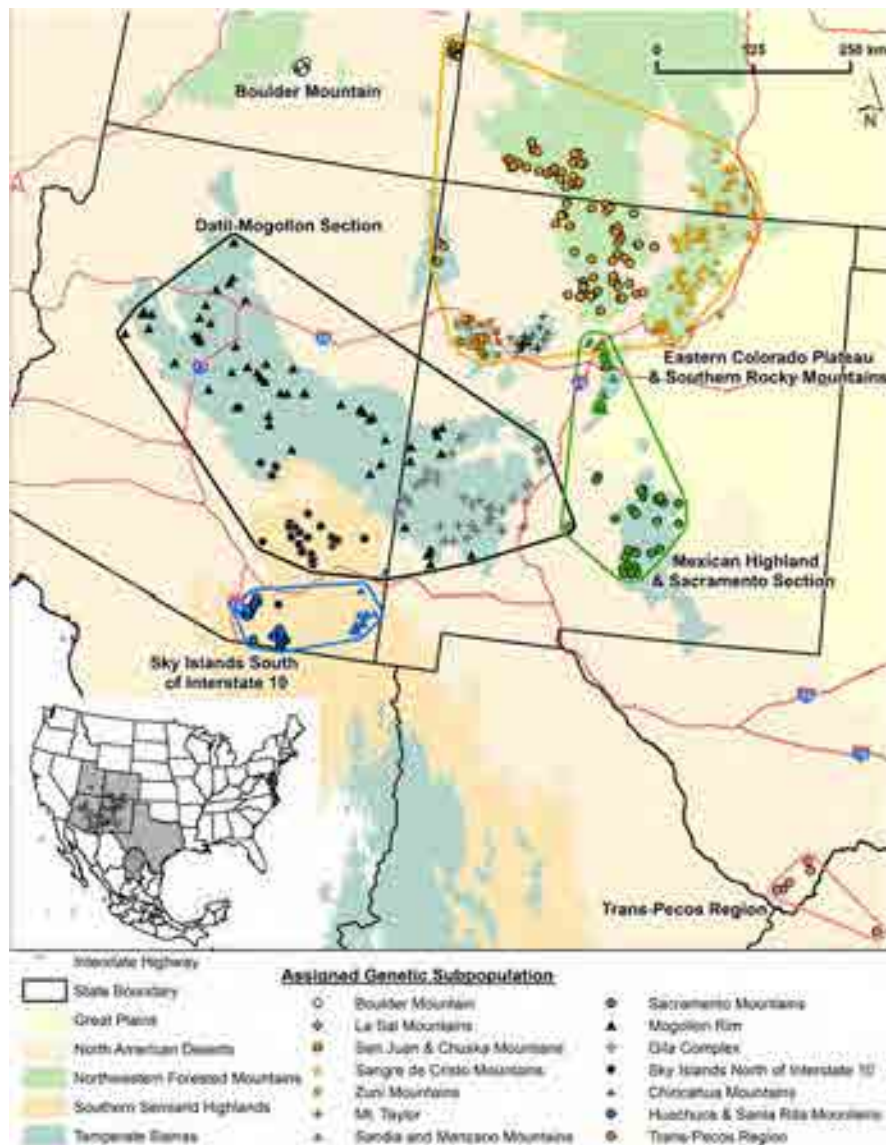

FIGURE 1 Distribution of genetic samples and subpopulations of American black bears (*Ursus americanus*) in the American Southwest and northern Mexico. GENELAND identified 6 and 14 subpopulations using the uncorrelated (polygons) and correlated (symbols) allele frequency models, respectively. The 6 larger subpopulations are named clusters.

Zaragoza and New Mexico. At present, black bears from the Trans-Pecos region have been documented in the Davis Mountains, Texas, ~150km south of black bears found in the Guadalupe Mountains on the New Mexico and Texas border. We genotyped all individuals using the ZFX-ZFY sex marker and 15 microsatellite loci (CXX20, G1A, G1D, G10B, G10C, G10H, G10J, G10L, G10M, G10O, G10P, G10U, G10X, MU50, and MU59; Durnin et al., 2007; Ostrander et al., 1993; Paetkau et al., 1998; Paetkau & Strobeck, 1995; Taberlet et al., 1997). Wildlife Genetics International in Nelson, British Columbia, Canada, generated all genotypes. Detailed laboratory protocols for microsatellite amplification and assignment error can be found in Paetkau (2003) and Gould et al. (2018). We obtained permits under the Convention on International Trade in Endangered Species (Export Permits 12US86418A/9, 13US19950B/9, 13US199551B/9, 14US43944B/9, 15US61420B/9, 15US69493B/9, 15US69502B/9) to export samples to Canada for analysis. Our research was authorized by the New Mexico Department of Game and Fish (Taking Protected Wildlife for Scientific and or Education

Purposes Permit 3504) and approved by the New Mexico State University Institutional Animal Care and Use Committee (Protocol number 2011-027).

2.3 | Describing genetic structure and estimating gene flow

We conducted all genetic analyses in program R version 3.5.2 unless otherwise specified (R Core Team, 2018). We tested for linkage disequilibrium (LD) using the R package GENEPOP and null alleles and deviations from Hardy-Weinberg equilibrium (HWE) using the R package POPGENREPORT (version 3.0.0; Adamack & Gruber, 2014; version 1.0.5; Rousset et al., 2017). We conducted a significance test for null alleles by assessing if a bootstrapped 95% confidence intervals (CI) for each locus overlapped zero, whereby overlap would indicate that the frequency of null alleles does not differ significantly from zero. We applied a Bonferroni correction ($\alpha = 0.05$ divided by the number of

pairwise comparisons for each test) of $\alpha \leq 0.0005$ (LD) and $\alpha \leq 0.003$ (HWE) to reduce the likelihood of a false-positive significance test, and we generated allele-frequency statistics for each locus in POPGEN-REPORT. For each identified subpopulation, we quantified genetic diversity using unadjusted private alleles (A_p) and private alleles using rarefaction (A_{PR}), which accounts for differences in sample size among subpopulations, using HP-RARE v1.0 (Kalinowski, 2004, 2005). We also quantified genetic diversity by estimating expected (H_E) and observed (H_O) heterozygosity and allelic richness using rarefaction (A_R) with the R package DIVERSITY (version 1.9.9; Keenan et al., 2013). We used DIVERSITY to calculate deviations from random mating (F_{IS}) and genetic differentiation among subpopulations (F_{ST}) along with their 95% CI based on 1000 bootstrap iterations. We classified values of F_{ST} from 0.05–0.14, 0.15–0.24, and ≥ 0.25 as moderate, high, and very-high differentiation, respectively, and considered differentiation to be biologically meaningful if the lower CI was ≥ 0.05 (Hartl & Clark, 1997).

We used two Bayesian clustering programs to characterize population structure, GENELAND and STRUCTURE (Guillot et al., 2005; Pritchard, 2000). Both programs use multi-locus genotypes to infer the number of genetic subpopulations (K) maintaining both Hardy-Weinberg and linkage equilibrium. GENELAND, however, uses spatial data to infer the spatial boundaries that separate the K subpopulations (Guillot et al., 2005). Because GENELAND has been shown to outperform other Bayesian clustering methods in detecting barriers to dispersal in fewer generations for species with higher dispersal abilities (Blair et al., 2012; Safner et al., 2011), we based our inferences on GENELAND. Results from the STRUCTURE analysis were similar and are available, along with the methods, in Appendix S1. We performed 10 independent runs using the uncorrelated and correlated allele frequency models. We used both models because the former is less sensitive to departures from model assumptions while the latter is more apt to detect subtle genetic differentiation (Guillot et al., 2008; The Geneland Development Group, 2018). We varied K from 1 to 31 (the maximum number of sampling locations +1) and then used the model with the highest mean posterior probability to select K and assigned individuals to the population in which their estimated proportion of ancestry (i.e., the Q-value) was the greatest. We optimized all models using 500,000 Markov Chain Monte Carlo iterations, 1000 burn in, a 100-iteration thinning interval, an uncertainty of 2 km for GPS coordinates, and a maximum rate of 1650 nuclei for the Poisson-Voronoi tessellation (three times the number of individuals). We implemented our analysis in the R package GENELAND using program R (version 3.4.4; R Core Team, 2018; The Geneland Development Group, 2018). After assessing population structure, we again assessed for LD, null alleles, and deviations from HWE, and if these tests failed then we reassessed for population structure until tests were not significant.

2.3.1 | Environmental variables

Available food resources should influence habitat selection, as black bears must accumulate large-fat stores for both hibernation and

reproduction (Costello et al., 2003) and food for bears in arid environments is tied to precipitation (precip; Zlotin & Parmenter, 2008). Black bears are forest obligates and have evolved morphological and behavioral adaptations associated with exploiting forest stands (Herrero, 1972) and they require thermal refugia (Lara-Díaz et al., 2018) because they are susceptible to hyperthermia (Sawaya et al., 2017). We modeled these features using canopy height (canopy), percent canopy (percan), and water bodies (water) as canopy provides thermal cover and water is necessary for thermoregulation, especially if bears crossed more inhospitable land cover such as desert. Male black bears have been shown to use less rugged areas (Costello, 2010; Johnson et al., 2015; Onorato, Hellgren, Van Den Bussche, & Skiles Jr., 2004), so we used a Terrain Ruggedness Index (TRI) to represent potential movement corridors. Linear-water features (streams) contain food, escape, and thermal cover, and are travel corridors (Atwood et al., 2011; Johnson et al., 2015). Roads can elicit negative behavioral and genetic effects and can influence bear distribution (Dixon et al., 2007; Gould et al., 2019), so we assessed their effect by estimating road density (rd. density). Interstates and highways (rd. major), which if not acting as barriers, may inhibit gene flow by heightening mortality rates (Little et al., 2017). We did not explore the influence of other anthropogenic activities such as agriculture or human settlements because the former is uncommon and sparsely distributed across New Mexico while the latter is correlated with road density.

We determined the spatial extent of the environmental variables, and subsequent resistance surfaces, by buffering all sample locations by 61 km based on the maximum-dispersal distance for black bears in the Sangre de Cristo and Mogollon mountains, New Mexico (Costello, 2010). We calculated mean-summer precipitation (Apr-Sep; continuous covariate), using WorldClim2 monthly precipitation levels from 1970 to 2000 (<http://worldclim.org/version2>; Fick & Hijmans, 2017). We obtained percent canopy (continuous covariate) at a 30m resolution using the U.S Geological Survey Global Tree Canopy Cover dataset (<https://www.landcover.usgs.gov>; Hansen et al., 2013). We obtained canopy height (continuous covariate) at a 1 km resolution using the National Aeronautics and Space Administration EARTHDATA Spatial Data Access Tool (<https://daac.ornl.gov>). We obtained location data for streams (binary covariate) and water bodies (binary covariate) from the National Hydrography Dataset (<https://www.usgs.gov/core-science-systems/ngp/national-hydrography>). We derived TRI (continuous covariate) using a National Elevation Dataset 30m digital elevation model (www.nationalmap.gov) and the Benthic Terrain Modeler in ArcMAP. We calculated road density (km/25 km²; continuous covariate) and major roads (categorical covariate) using data from Open Street Map (www.openstreetmap.org). For major roads, we used three classifications: interstate highways, state highways, and county roads. We resampled each resistance layer to a 5 km resolution using bilinear interpolation to reduce the computational intensity of the optimization process given the large extent of the study area without sacrificing an accurate characterization of the landscape (McRae et al., 2008).

We created and manipulated all resistance surfaces using ArcMAP v10.4.1 (Environmental Systems Research Institute, Redlands, CA, USA). We assessed correlation among covariates using a Pearson's correlation coefficient of $r \geq |0.60|$. We found a correlation between canopy height and percent canopy ($r = 0.72$) and removed the latter from our analysis.

2.3.2 | Generating the resistance surface

We used the R package *RESISTANCEGA* to optimize resistance surfaces, assess the effect of pairwise-effective distance on pairwise-genetic distance, and conduct model selection while accounting for non-independence among the pairwise data (version 4.1-0.2.1; Peterman, 2018; Peterman et al., 2014). *RESISTANCEGA* optimizes resistance surfaces using a genetic algorithm (a process based on the theory of natural selection) that eliminates the subjective assignment of resistance values by expert opinion and the limited exploration of the optimized parameter space (Peterman, 2018; Peterman et al., 2014). The optimization process begins with the selection of parameter values that control the transformation, shape of the transformation, and resistance value for a continuous surface, or if a categorical surface, the assignment of values to each resistance level. After each iteration, pairwise effective distances among all individuals are calculated and a linear mixed-effects model is then fit to the data where effective distance is used to predict genetic distance among individuals (Clarke et al., 2002; Peterman, 2018; Peterman et al., 2014). The relative support for the combination of parameter values at each iteration is assessed using an objective function from the mixed-effects model, and once the objective function can no longer be improved, surface optimization is completed.

We quantified effective landscape distance using random-walk commute times in the R package *GDISTANCE* (version 1.2-2; Van Etten, 2017). We quantified pairwise-genetic distance using the individual-based metric proportion of shared alleles (D_{ps}) in the R package *ADEGENET* (version 2.1.1; Jombart, 2008). We applied a monomolecular and Ricker transformation along with their inverse, reverse, and inverse-reverse forms to each continuous-resistance covariate to explore the functional relationship between each covariate and resistance to movement. We constructed our model using a maximum of three covariates due to computational intensity and assessed the relative support among resistance surface models using Akaike's Information Criterion adjusted for small sample size (AICc) with models >2 AICc units from the top model being discounted (Burnham & Anderson, 2002; Hurvich & Tsai, 1989) and by calculating the model weight (w_i). We conducted the optimization process in program R (version 3.4.4; R Core Team, 2017) using the Bridges high-performance computing system at the Pittsburgh Supercomputing Center (Nystrom et al., 2015; Towns et al., 2014).

To explore how geographic distance vs. landscape distance affects pairwise-genetic distance, we used AICc to rank the fit of linear mixed-effects models using Euclidean distance, the top-ranked resistance surface, and a model that combined both.

2.3.3 | Relative degree and direction of gene flow

We investigated asymmetric gene flow by estimating relative migration among the estimated subpopulations using the *divMigrate* function in the R package *DIVERSITY* where maximum relative gene flow is set at 1 and minimum at 0 (Keenan et al., 2013; Sundqvist et al., 2016). We calculated G_{ST} , a measure of population differentiation and an analog of F_{ST} , for network plots, conducted 1000 bootstrap iterations to generate 95% CIs to evaluate if asymmetric gene flow was significant and chose to display connections ≥ 0.50 .

3 | RESULTS

3.1 | Describing genetic structure

We genotyped 550 (285M:265F) individuals from 28 localities (Appendix S2: Table S1). We found a moderate percentage of null alleles (4–12%) across all loci in this total sample (Appendix S2: Table S2). We found 82% of the pairwise comparisons among loci ($n = 105$) for LD to be significant ($P < 0.0005$ after Bonferroni correction) and all loci were out of HWE ($p < .003$ after Bonferroni correction; Appendix S2: Tables S3–S4). These metrics suggest that genetic structuring may occur among black bears across the Southwest.

The uncorrelated allele frequency model in *GENELAND* identified 6-regional genetic clusters: Boulder Mountain, Utah (BM), the eastern Colorado Plateau and Southern Rocky Mountains (ECPSRM), the Datil-Mogollon Section (DMS), the Mexican Highland and Sacramento sections (MHSS), the Sky Islands south of Interstate 10 (SIS), and the Trans-Pecos region (TP; Figure 1; Appendix S2: Figure S1). The presence of null alleles was suggested at loci CXX20 (BM), G10H (ECPSRM), G10J (SIS and TP), G10O (MHSS and SIS), and MU50 (BM and DMS; Appendix S3: Table S1). We found the CXX20 locus to be non-randomly associated with G10B and G10H in the BM subpopulation (Appendix S3: Tables S2–S4). The G10U and G10L loci were out of HW proportions in the ECPSRM and DMS, respectively (Appendix S3: Table S5). The presence of null alleles and linkage disequilibrium suggests these loci may not accurately represent genetic structure and diversity while deviations from HW proportions suggest there could be additional genetic structure that was not detected under the uncorrelated allele frequency model.

Allelic richness was lowest in the SIS ($A_R = 3.91$) and highest in the DMS ($A_R = 5.43$); the TP had the second highest allelic richness despite small sample size (Table 1). The number of private alleles using rarefaction was lowest in DMS ($A_{PR} = 0.09$) and highest in the TP ($A_{PR} = 1.79$; Table 1; Appendix S3: Table S6). Observed heterozygosity ranged from 0.42 to 0.64 was slightly lower than H_E (0.44–0.62) for all regional subpopulations except for the TP (Table 1). The F_{IS} estimates suggested deviations from random mating within the ECPSRM and DMS subpopulations, but along with H_O being lower than H_E for both subpopulations, it is more likely that a Wahlund effect, rather than nonrandom mating, is occurring, which indicates greater substructure within these two regions (Wahlund, 1928).

TABLE 1 Number of individuals (N), private alleles (A_P), private alleles using rarefaction (A_{PR}), allelic richness using rarefaction (A_R), observed (H_O) and expected (H_E) heterozygosity, and a measure of deviations from random mating (F_{IS}) and its 95% confidence interval (LCI and UCI) based on 1000 bootstrap iterations for American black bear (*Ursus americanus*) subpopulations in the American Southwest and northern Mexico.

Notes: Bolded values signify statistically significant differentiation.

Abbreviations: BM, Boulder Mountain; DMS, Datil-Mogollon Section; ECPSRM, Eastern Colorado Plateau and Southern Rocky Mountains; MHSS, Mexican Highland and Sacramento sections; SIS, Sky Islands South of Interstate 10; TP, Trans-Pecos.

Genetic differentiation was the lowest between the ECPSRM and DMS ($F_{ST} = 0.03$) and highest between the TP and SIS ($F_{ST} = 0.44$). Overall, the two most isolated subpopulations, BM and the TP, displayed the highest levels of genetic differentiation compared to all other subpopulations (Table 2).

The correlated allele frequency model identified 14-genetic clusters that closely tracked the sampled mountain ranges (Appendix S2:

Figure S1). The BM and TP subpopulations from the regional results remained while the larger clusters were broken down into 12 subpopulations (Figure 1). We did not find evidence of null alleles (Appendix S4: Table S1–S8). All loci within each respective subpopulation were in HWE (Appendix S4: Table S9). Because there was no discernable pattern of null alleles, LD, or HW disequilibrium for ≥ 1 locus at ≥ 1 subpopulation we retained all loci in our analyses (Morin et al., 2010).

The TP subpopulation retained the highest number of private alleles ($A_{PR} = 1.39$) while the Mogollon Rim (MR) was estimated to have the least number of private alleles ($A_{PR} = 0.01$; Table 1). The Chiricahua complex (CHC) and the Huachuca-Santa Rita mountains (HSRM) subpopulations both exhibited a fixed allele (122bp) at the MU50 locus (Appendix S4: Table S10), these two subpopulations are south of Interstate 10. Heterozygosity was lowest in the HSRM and highest in the TP (Table 1). The F_{IS} estimates did not suggest deviations from random mating (Table 1). Pairwise differentiation was high or very-high when subpopulations were compared to the BM, HSRM, and TP subpopulations ($F_{ST} \geq 0.15$; Table 3), this was not unexpected as both the BM and TP populations are isolated from the other populations. The La Sal Mountains (LSM), another somewhat isolated subpopulation along the Utah–Colorado border, was moderately differentiated from all other subpopulations except for three subpopulations to the south: the Sangre de Cristo Mountains (SCM), the San Juan and Chuska mountains (SJC), and Zuni Mountains (ZM; Table 3), all relatively close geographically. Genetic differentiation was low to moderate among the remaining subpopulations (Table 3).

3.2 | Landscape features regulating gene flow

The top-ranked resistance-surface model was well supported ($w_i = 1.00$), substantially outperformed the second-ranked model ($\Delta AIC_c = 47.18$), and included canopy, precipitation, and TRI (Appendix S5: Tables S1 and S2). The transformations that best represented the relationship between canopy, precipitation, and TRI with resistance to movement were the inverse monomolecular, inverse Ricker, and monomolecular, respectively, indicating that resistance decreased as canopy increased, decreased as precipitation increased until the covariate reached moderate levels at which point resistance started to increase, and increased as TRI increased (Table 4). More simply, resistance was lowest in areas with higher forest canopy, higher levels of precipitation, and less rugged landscapes. Precipitation contributed the most to the top-ranked resistance surface (58%) followed by canopy (40%) with a small contribution from TRI (2%). This top-ranked model received considerable support when compared to Euclidean distance alone, suggesting isolation by resistance better explained the observed-genetic pattern than isolation by distance (Table 4). A model composed of both effective and Euclidean distance, however, outperformed ($w_i = 1.00$) the top-ranked resistance model suggesting isolation by distance is still an important component explaining genetic distance (Table 4). Our analysis did not show support for any resistance-based models that included road density or major roads (Appendix S5: Tables S1 and S2).

3.3 | Relative degree and direction of genetic connectivity

The directional relative migration network-clustered populations in the northern part of our study region along the Colorado–New

Mexico border (ECPSRM) with populations located in the central portions of our study region, in the states of Arizona and New Mexico (DMS and MHSS), suggesting high rates of gene flow among these regional subpopulations. Estimated gene flow among the remaining subpopulations was low as most of the pairwise-relative migration values (87%) were half of that occurring between the highest values from central Arizona and western New Mexico (DMS) to the Colorado–New Mexico border (ECPSRM; Figure 2; Appendix S3: Figure S1; Appendix S3: Table S7). There was a pronounced south-to-north linkage pattern of asymmetric gene flow from central Arizona and western New Mexico (DMS) to the Colorado–New Mexico border (ECPSRM) and central New Mexico (MHSS), from southern Arizona (SIS) to central New Mexico (MHSS), and from Texas and northern Mexico (TP) to the Colorado–New Mexico border (ECPSRM; Figure 2; Appendix S3: Figure S1; Appendix S3: Table S7). The mountain range subpopulations exhibited a similar pattern with subpopulations from the central portion of the study area clustering together and asymmetric gene flow in a northward direction (Figures 1 and 3; Appendix S4: Figure S1; Appendix S4: Table S11).

4 | DISCUSSION

Our study further supports the hypothesis that the Southwest served as a fourth Pleistocene refugium for the American black bear during the LGM and that their present-day genetic structure is most likely a result of vicariant events as habitat fragmentation occurred when glaciers receded post-LGM. The Trans-Pecos population originated from the Sierra Madre Oriental, a north to south running mountain range in northeast Mexico, and is more closely related to the eastern lineage of black bears that occupied the American Southeast refugium (Onorato, Hellgren, Van Den Bussche, & Doan-Crider, 2004). The other more westerly populations would have likely arisen from the Sierra Madre Occidental, a parallel mountain range in western Mexico that is separated from the Sierra Madre Oriental by the Chihuahuan Desert (Varas-Nelson, 2010). Our sampled populations were highly structured with those from central Arizona, central New Mexico, and southern Colorado clustering together; these populations were distinct but related to populations within the Sky Islands border region and all of these populations were distinct from Trans-Pecos and Boulder Mountain. Populations would be expected to show genetic structure if repeated episodes of isolation and admixture occurred, driven by changes in habitat distribution.

4.1 | The influence of forest refugia on genetic structure

Our analyses supported the hypothesis that the current genetic structure is a consequence of Pleistocene–Holocene vicariance whereby bears occupied forest refugia during the LGM, but then followed changes in the distribution of forests as the Holocene dried

TABLE 3 Estimated pairwise genetic differentiation (F_{ST}) and their 95% confidence intervals based on 1000 bootstrap iterations for mountain range subpopulations identified by GENELAND using the correlated allele frequency model for American black bears (*Ursus americanus*) in the American Southwest and northern Mexico.

and warmed (Pleistocene–Holocene Vicariance Hypothesis). The Southwest likely served as a refugium for black bears during various periods in the Pleistocene and Holocene when habitats in more northerly latitudes were dominated by more cold-adapted plant species that black bears do not typically use (Betancourt et al., 1990). Paleoeological reconstruction reveals considerable forest habitat available to black bears throughout the Southwest. This forest was widespread and found throughout lower elevation areas in what is currently Chihuahuan and Sonoran desert. In certain areas, these forested habitats were stable for 10,000–20,000 years, and were often found at lower elevations than they are today (Holmgren et al., 2006; McAuliffe & Van Devender, 1998; Van Devender, 1990a,

1990b). As climates aridified, forest habitats either moved up in elevation, moved north dependent upon precipitation patterns, soil moisture regimes, and winter temperatures, or both. Evidence of these expansion and isolation events can also be found in the fossil record. Fossil specimens identified as modern day black bear have been discovered at 12 relatively low-elevation Pleistocene sites (mean = 1495 m; range = 1171–1716 m) dated to the mid- and late-Wisconsin age (~11,000–65,000 BP) within the present day Chihuahuan and Sonoran deserts (Harris, 1987, 1989, 1993, 2003; Messing, 1986; Saunders, 1977; Skinner, 1942; Slaughter, 1975). Thus, for much of the late Pleistocene and into the early Holocene, the dominant paleovegetation community of the region was a

Notes: We ranked models by the difference in AIC_c (ΔAIC_c) between the top model and competing models and evaluated model support using model weights (w_i). Optimization results are also reported including the percent contribution of each covariate to the total surface resistance (Contribution), transformation applied to each covariate (Transformation) along with the shape and magnitude of each transformed covariate.

piñon-juniper-oak woodland that black bears inhabited, similar to the plant community selected by black bears in the Sky Islands today (Onorato et al., 2003). The isolated Sky Island mountain ranges, currently inhabited by black bears, were most likely functionally connected by this piñon-juniper-oak woodland (Van Devender, 1990a).

Black bears are omnivorous, but vegetation, fruits, and nuts comprise 70–90% of the diet, supplemented with insects and vertebrates (Delgadillo Villalobos et al., 2019). In spring, they feed on grasses and other vegetation, in mid-late summer on soft mast, such as berries, and in late summer–fall prior to hibernation they forage on hard mast, such as acorns and piñon pine nuts (Beck, 1991; Costello et al., 2001; Onorato et al., 2003). In lower elevations within the Southwest, they also feed on sotol (*Dasyliion* spp.), yucca (*Yucca* spp.), and prickly pear cactus (*Opuntia* spp.; Delgadillo Villalobos et al., 2019). Although found in semiarid shrublands, black bears are primarily a forest-adapted species and forests are important habitats across their range (Evans et al., 2017; Gould et al., 2019; Onorato et al., 2003). Thus, it stands to reason that black bears would track the abundance of their main food over the short term, which would explain contemporary movements and dispersal patterns and populations would track the distribution of their primary habitat over the long term, which would explain species distribution and population genetic structure.

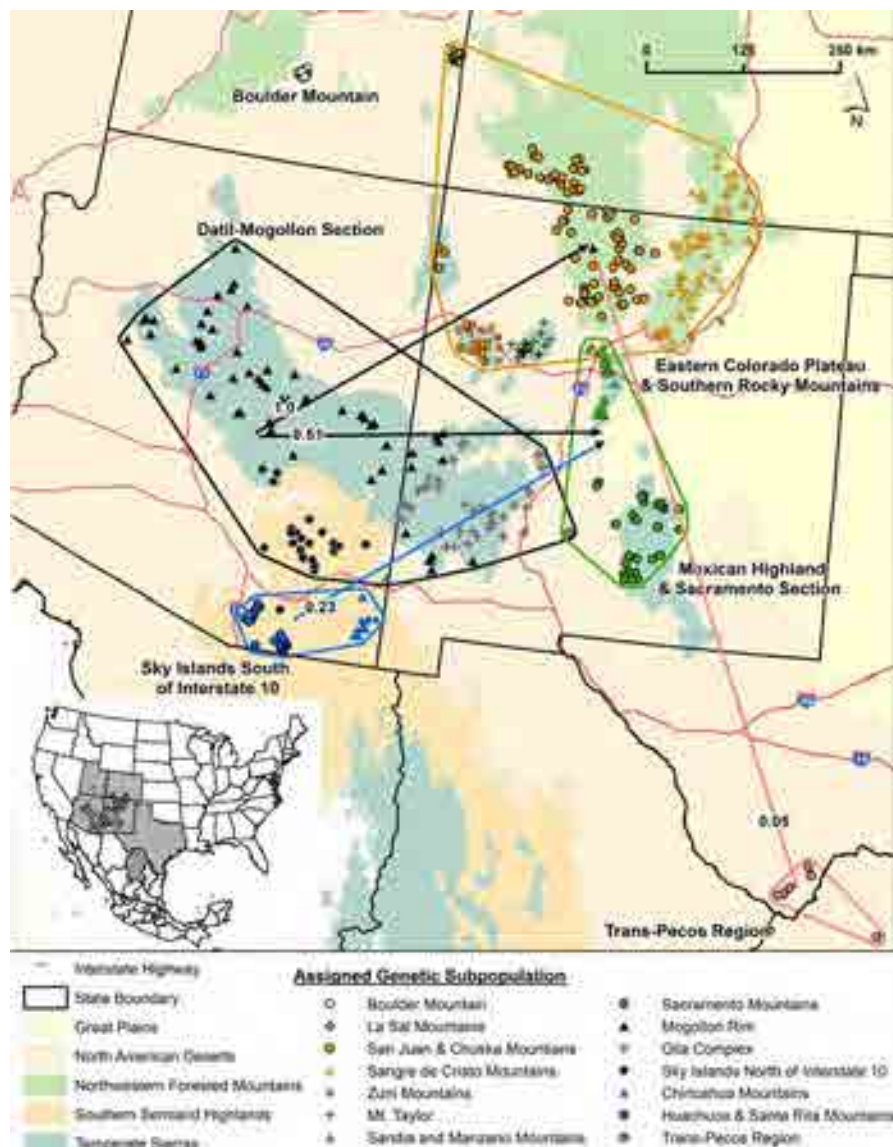

4.2 | The influence of transportation infrastructure on genetic structure and gene flow

Our analyses did not support the hypothesis that interstate highways are limiting the movement of black bears across the Southwest

(Anthropocene Filter Hypothesis). The uncorrelated allele frequency model failed to detect such a genetic pattern at the regional level and the correlated frequency model often clustered bears together that were on opposite sides of major interstates. For example, bears from the Mogollon Rim (MR) population in Arizona were found on both sides of Interstates 17 and 40; bears from the Zuni Mountains (ZM) population in New Mexico also clustered together from both sides of Interstate 25 and 40; bears from the Sandia and Manzano mountains (SMM) population in New Mexico were found on both sides of Interstate 40; bears from the Gila complex (GC) in New Mexico were found on both sides of Interstate 25, although primarily to the west; and bear populations from the Sky Islands North of Interstate 10 (SIN) and from the Chiricahua complex (CHC) of Arizona were found on both sides of Interstate 10.

Roads, urbanization, and interstate highways can negatively influence carnivore populations and the size of the interstate (e.g., number of traffic lanes) and relative traffic flow may be contributing factors as well (Riley et al., 2014; Serieys et al., 2015). Perhaps one of the most extreme cases has occurred in the Santa Monica Mountains of southern California where the morass of urbanization and grand thoroughfares has restricted population size and caused degradation in genetic variation in mountain lions (*Puma concolor*; Riley et al., 2014). Although bear resource use is negatively affected by roads (Gould et al., 2019), the effect of roads on bear movements and gene flow varies across their range. Roads had little effect on movements in remote areas such as in Idaho (Cushman et al., 2006) but had major impacts on movement patterns and genetic structure in more heavily urbanized areas such as Florida (Dixon et al., 2007; McCown et al., 2009). The highways in the Southwest receive less

FIGURE 2 Directional relative migration network based on G_{ST} values for American black bear (*Ursus americanus*) subpopulations in the American Southwest and northern Mexico. The network visualized shows significant asymmetrical migration values for subpopulations identified using the uncorrelated allele frequency model in program GENELAND.

traffic volume and are narrower than heavily populated areas like California or Florida, so their impedance to bear movement would be expected to be reduced. Riparian underpasses could also focus movement across Southwest highways as bears are less likely to traverse the desert scrub matrix and are more likely to be close to streams (Jensen et al., 2022). Furthermore, black bears have a relatively long generation time and interstate highways are recent, anthropogenic barriers or filters, and their current genetic structure may not reflect the impact of interstate highways as there has been insufficient time for populations to diverge among those bisected by interstates (Blair et al., 2012; Epps et al., 2005; Safner et al., 2011).

A handful of observed long-distance and cross-interstate movements by bears supports the hypothesis that interstates in the Southwest are not yet a barrier to bear movement and thus have most likely not influenced gene flow. We genotyped five individuals (three males and two females) that we identified as being approximately 90km, 150km, 300km, and 360km away from where they were originally captured, collected, or detected by collaborating agencies. These observed movements required the individuals

to cross Highway 70, Interstate 25, or Interstate 40. Finally, Liley and Walker (2015) placed a GPS collar on a male bear on the New Mexico–Colorado border that subsequently traveled to central Colorado and crossed Interstate 25 twice before returning to New Mexico, a cumulative distance of 1482 km. These observations show that bears in the Southwest can travel long distances and cross both highways and interstates when doing so.

4.3 | The scale of population genetic structure in Southwestern black bear populations

Regionally, subpopulation boundaries followed the distribution of three major ecoregions (Omernik & Griffith, 2014): the Northwestern Forested Mountains contained populations in the Eastern Colorado Plateau and Southern Rocky Mountains (ECPSRM) and Boulder Mountain, Utah (BM); the Temperate Sierras harbored bears from the Datil-Mogollon Section (DMS) and the Mexican Highlands and Sacramento Section (MHSS); and

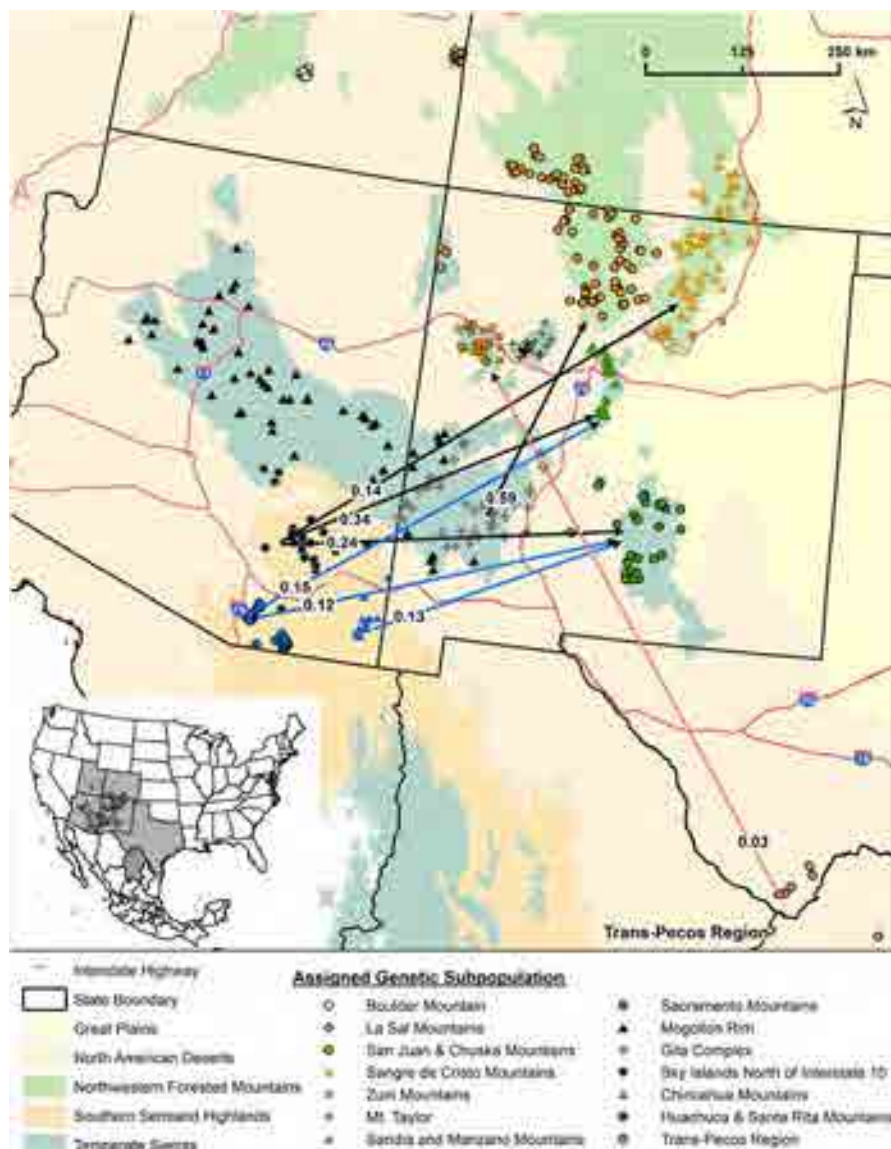

FIGURE 3 Directional relative migration network based on G_{ST} values for American black bear (*Ursus americanus*) subpopulations in the American Southwest and northern Mexico. The network visualized shows significant asymmetrical migration values for subpopulations identified using the correlated allele frequency model in program GENELAND.

the Southern Semi-Arid Highlands contained populations from the Sky Islands South of Interstate 10 (SIS). Low genetic differentiation and relatively high gene flow among the three largest subpopulations suggest these subpopulations (ECPSRM, DMS, and MHSS) form the core contemporary Southwest black bear population. The SIS in southern Arizona shows moderate differentiation from this core population, which is surprising given their proximity (distance between the SIS and the DMS is ~20km) and is likely due to the relatively inhospitable habitat matrix separating the Sky Islands region from other subpopulations. The Sky Islands are a series of “montane islands separated by a desert sea” where the intervening landscape matrix of primarily Chihuahuan or Sonoran desert acts as a semi-permeable barrier to black bear dispersal and gene flow (Lomolino et al., 1989). Atwood et al. (2011) also found genetic substructure among black bear populations along the US–Mexico border within the Sky Islands region.

There was a relatively high degree of genetic differentiation when comparing Boulder Mountain, Utah and the Trans-Pecos

region in west Texas and northeast Mexico to the other Southwest subpopulations. We believe this differentiation is due to genetic isolation rather than incomplete sampling. The origination of the Boulder Mountain population is more enigmatic and more information is needed to determine if it is a product of eastward expansion by populations from the Pacific Northwest refugium or through the expansion and isolation of populations from the north (Lackey et al., 2013; Malaney et al., 2018; Puckett et al., 2015).

We had a small sample from the Trans-Pecos region, but that subpopulation had the highest allelic richness, the highest observed heterozygosity, many private alleles, and some private alleles occurred at high frequency, indicating a period of isolation and genetic differentiation followed by little to no connectivity (Slatkin, 1985). The existence of private alleles in the Trans-Pecos region is most likely a product of isolation followed by bears recolonizing west Texas from the Sierra Madre Oriental (Onorato et al., 2007; Onorato, Hellgren, Van Den Bussche, & Doan-Crider, 2004). Bears in the Sierra Madre Occidental are genetically distinct from those in the Sierra Madre Oriental

(Varas-Nelson, 2010). The high levels of genetic diversity may partly be a product of migration-dispersal events due to hard mast crop failure in Big Bend National Park, Texas. Those events resulted in the movement of bears back to the Sierra del Carmen, Mexico, and invariably subsequent movements back to west Texas (Onorato et al., 2003; Onorato, Hellgren, Van Den Bussche, & Doan-Crider, 2004).

The unique genetic variation of the Trans-Pecos subpopulation also reflects the ancestral relationship between the eastern Mexican and eastern American black bear populations that are hypothesized to have occupied the American Southeast refugium before diverging 67–31 kya (Pedersen et al., 2021, Van Den Bussche et al., 2009). Pedersen et al.'s (2021) hypothesis that gene flow between black bear populations in the Sierra Madre Occidental and Oriental was inhibited by the Chihuahuan Desert conflicts with paleomidden evidence that shows pygmy conifer woodlands dominated the present-day Chihuahuan Desert during the Pleistocene (Betancourt et al., 1990). Furthermore, black bear fossils have been discovered at low-elevation Pleistocene caves dated to ~11,000–65,000 BP within the present-day Chihuahuan Desert (Harris, 1987, 1989, 1993, 2003; Messing, 1986; Saunders, 1977; Slaughter, 1975). These caves could be sampled for ancient environmental DNA or ancient DNA could be amplified from the fossils themselves to further our understanding of the distribution of refugia and the movements and genetic structure of bears in the American Southwest and northern Mexico.

4.4 | The influence of landscape resistance and geographic distance on gene flow

Our estimates of the relative degree and direction of gene flow also suggested that gene flow occurred from south to north and was high among the regionally central subpopulations where contiguous forest existed. Limited gene flow among these central subpopulations and the southern Madrean Sky Island Archipelago appeared to be filtered by the mosaic of less hospitable habitat found in the lowlands. The relative degree of gene flow was also affected by the geographic distance among subpopulations. The Boulder Mountain, Utah population (BM) and the Trans-Pecos population in west Texas and northeast Mexico (TP) were isolated from the other populations and showed little gene flow with them. This pattern was not unexpected as ~200 km of the Colorado Plateau and ~430 km of the Chihuahuan Desert separates the BM and TP populations from their nearest subpopulation, respectively.

The consistent pattern of asymmetric gene flow northward is indicative of prehistoric range expansion. Varas-Nelson (2010) noted a similar pattern in northern Mexico where the migration rate from Sierra El Nido in Sonora to Sierra San Luis in Chihuahua, ~250 km to the north, was 2.5× greater than the migration rate southward. Northward expansion also supports previous research that postulated that the Southwest refugium dominated the genetic assemblage of the Intermountain West before admixing along the US–Canada border with bears that originated from the Great Lakes region (Pelletier et al., 2011; Puckett et al., 2015).

Our resistance-based models of gene flow revealed that areas with higher canopy cover and precipitation, essentially forested habitats, were associated with higher rates of gene flow and within these areas, gene flow was facilitated by less rugged areas. Gene flow was also affected by geographic distance. Thus, populations connected by contiguous forest had high gene flow (e.g., Eastern Colorado Plateau and Southern Rocky Mountains, Datil-Mogollon Section, Mexican Highlands, and Sacramento Section) and populations separated by desert and isolated by distance had lower gene flow (e.g., Trans-Pecos and Boulder Mountain). Because female black bears are highly philopatric, the effect of distance on gene flow may be governed by their behavior, but also mediated by long-distance dispersal events by male bears with male bears also having been shown to select against ruggedness (Apps et al., 2006; Johnson et al., 2015; Lara-Díaz et al., 2018; Pelletier et al., 2011). So, it appears that habitat most likely acts as a conduit (e.g., forest) or filter (e.g., desert) to bear movement and that geographic distance plays an important role owing to intersexual differences in movement behavior.

4.5 | Conservation implications

American black bears in the Southwest occupy a naturally fragmented landscape with low-density subpopulations linked together into a metapopulation (Gould et al., 2018; Onorato, Hellgren, Van Den Bussche, & Doan-Crider, 2004). Habitat loss and fragmentation owing to climate change, anthropogenic land use, and US–Mexico border security could increase the extinction risk of individual subpopulations and sever linkages among key subpopulations within the metapopulation (Lara-Díaz et al., 2021).

Climate change is contributing to a rise in aridity and temperature in the Southwest and has led to increases in insect outbreaks, intense droughts, and catastrophic wildfires resulting in substantial tree mortality reducing the distribution and quality of bear habitat over the long term (Gould et al., 2019; Thorne et al., 2018; Williams et al., 2010). Increasing human development and population growth is likely to increase human population density and traffic rates resulting in higher rates of road mortality, which could lower genetic connectivity and enhance fragmentation, heightening the extinction risk for some subpopulations (Dixon et al., 2007; Ernest et al., 2014; Riley et al., 2014). Finally, the US–Mexico border wall poses a threat to the persistence of bears in the Southwest. The current border wall spans ~1125 km, and in the recent past, the US government proposed to increase the length of the border wall and change vehicle barriers that are permeable to bears, to impassable pedestrian barriers that would impede cross-border migration and dispersal (4–10 m tall, 5–10 cm wide gaps; Flesch et al., 2010). The current wall and more impenetrable barriers could sever linkages between populations in the Sierra Madre Occidental of northern Mexico with those in southern Arizona and New Mexico (Atwood et al., 2011; Varas-Nelson, 2010) and the Sierra Madre Oriental of northern Mexico with those in west Texas (Hellgren et al., 2005; Onorato, Hellgren,

Van Den Bussche, & Doan-Crider, 2004). Binational collaboration between the United States and Mexico could be crucial to the future persistence and viability of the black bear metapopulation in southwestern North America and represents a unique conservation opportunity.

About the Cooperator Science Series:

The [Cooperator Science Series](#) was initiated in 2013. Its purpose is to facilitate the archiving and retrieval of research project reports resulting primarily from investigations supported by the [U.S. Fish and Wildlife Service \(FWS\)](#), particularly the [Wildlife and Sport Fish Restoration Program](#). The online format was selected to provide immediate access to science reports for FWS, state and tribal management agencies, the conservation community, and the public at large.

All reports in this series have been subjected to a peer review process consistent with the agencies and entities conducting the research. For U.S. Geological Survey authors, the peer review process (<http://www.usgs.gov/usgs-manual/500/502-3.html>) also includes review by a bureau approving official prior to dissemination. Authors and/or agencies/institutions providing these reports are solely responsible for their content. The FWS does not provide editorial or technical review of these reports. Comments and other correspondence on reports in this series should be directed to the report authors or agencies/institutions. In most cases, reports published in this series are preliminary to publication, in the current or revised format, in peer reviewed scientific literature. Results and interpretation of data contained within reports may be revised following further peer review or availability of additional data and/or analyses prior to publication in the scientific literature.

The [Cooperator Science Series](#) is supported and maintained by the FWS, [National Conservation Training Center](#) at Shepherdstown, WV. The series is sequentially numbered with the publication year appended for reference and started with Report No. 101-2013. Various other numbering systems have been used by the FWS for similar, but now discontinued report series. Starting with No. 101 for the current series is intended to avoid any confusion with earlier report numbers.

The use of contracted research agencies and institutions, trade, product, industry or firm names or products or software or models, whether commercially available or not, is for informative purposes only and does not constitute an endorsement by the U.S. Government.

Contractual References:

This document was developed in conjunction with the New Mexico Cooperative Fish and Wildlife Research Unit to fulfill reporting requirements for Federal Aid in Wildlife Restoration Project W93 R56 2.0. Previously published documents that partially fulfilled any portion of this contract are referenced within, when applicable. (USGS IPDS #: IP-074771).

EXECUTIVE SUMMARY

During the 2004–2005 to 2015–2016 hunting seasons, the New Mexico Department of Game and Fish (NMDGF) estimated black bear abundance (*Ursus americanus*) across the state by coupling density estimates with the distribution of primary habitat generated by Costello et al. (2001). These estimates have been used to set harvest limits. For example, a density of 17 bears/100 km² for the Sangre de Cristo and Sacramento Mountains and 13.2 bears/100 km² for the Sandia Mountains were used to set harvest levels. The advancement and widespread acceptance of non-invasive sampling and mark-recapture methods, prompted the NMDGF to collaborate with the New Mexico Cooperative Fish and Wildlife Research Unit and New Mexico State University to update their density estimates for black bear populations in select mountain ranges across the state.

We established 5 study areas in 3 mountain ranges: the northern (NSC; sampled in 2012) and southern Sangre de Cristo Mountains (SSC; sampled in 2013), the Sandia Mountains (Sandias; sampled in 2014), and the northern (NSacs) and southern Sacramento Mountains (SSacs; both sampled in 2014). We collected hair samples from black bears using two concurrent non-invasive sampling methods, hair traps and bear rubs. We used a gender marker and a suite of microsatellite loci to determine the individual identification of hair samples that were suitable for genetic analysis. We used these data to generate mark-recapture encounter histories for each bear and estimated density in a spatially explicit capture-recapture framework (SECR). We constructed a suite of SECR candidate models using sex, elevation, land cover type, and time to model heterogeneity in detection probability and the spatial scale over which detection probability declines. We used Akaike's Information Criterion corrected for small sample size (AIC_c) to rank and select the most supported model from which we estimated density.

We set 554 hair traps, 117 bear rubs and collected 4,083 hair samples. We identified 725 (367 M, 358 F) individuals; the sex ratio for each study area was approximately equal. Our density estimates varied within and among mountain ranges with an estimated density of 21.86 bears/100 km² (95% CI: 17.83 – 26.80) for the NSC, 19.74 bears/100 km² (95% CI: 13.77 – 28.30) in the SSC, 25.75 bears/100 km² (95% CI: 13.22 – 50.14) in the Sandias, 21.86 bears/100 km² (95% CI: 17.83 – 26.80) in the NSacs, and 16.55 bears/100 km² (95% CI: 11.64 – 23.53) in the SSacs. Overall detection probability for hair traps and bear rubs, combined, was low across all study areas and ranged from 0.00001 to 0.02. We speculate that detection probabilities were affected by failure of some hair samples to produce a complete genotype due to UV degradation of DNA, and our inability to set and check some sampling devices due to wildfires in the SSC. Ultraviolet radiation levels are particularly high in New Mexico compared to other states where NGS methods have been used because New Mexico receives substantial amounts of sunshine, is relatively high in elevation (1,200 m – 4,000 m), and is at a lower latitude. Despite these sampling difficulties, we were able to produce density estimates for New Mexico black bear populations with levels of precision comparable to estimated black bear densities made elsewhere in the U.S.

Our ability to generate reliable black bear density estimates for 3 New Mexico mountain ranges is attributable to our use of a statistically robust study design and analytical method.

There are multiple factors that need to be considered when developing future SECR-based density estimation projects. First, the spatial extent of the population of interest and the smallest average home range size must be determined; these will dictate size of the trapping array and spacing necessary between hair traps. The number of technicians needed and access to the study areas will also influence configuration of the trapping array. We believe shorter sampling occasions could be implemented to reduce degradation of DNA due to UV radiation; this might help increase amplification rates and thereby increase both the number of unique individuals identified and the number of recaptures, improving the precision of the density estimates. A pilot study may be useful to determine the length of time hair samples can remain in the field prior to collection. In addition, researchers may consider setting hair traps and bear rubs in more shaded areas (e.g., north facing slopes) to help reduce exposure to UV radiation. To reduce the sampling interval it will be necessary to either hire more field personnel or decrease the number of hair traps per sampling session. Both of these will enhance detection of long-range movement events by individual bears, increase initial capture and recapture rates, and improve precision of the parameter estimates. We recognize that all studies are constrained by limited resources, however, increasing field personnel would also allow a larger study area to be sampled or enable higher trap density.

In conclusion, we estimated the density of black bears in 5 study areas within 3 mountains ranges of New Mexico. Our estimates will aid the NMDGF in setting sustainable harvest limits. Along with estimates of density, information on additional demographic rates (e.g., survival rates and reproduction) and the potential effects that climate change and future land use may have on the demography of black bears may also help inform management of black bears in New Mexico, and may be considered as future areas for research.

INTRODUCTION

Setting sustainable harvest limits for game species is one of the main duties of state wildlife management agencies. To this end, state agencies spend a large portion of their annual budget on population surveys to estimate abundance and population trends of game animals. Survey methodologies for large ungulates are well developed and can provide relatively robust estimates of common game species such as deer (*Odocoileus* spp.) and elk (*Cervus canadensis*). In contrast, estimating the abundance or density of large carnivores like American black bears (*Ursus americanus*), which are cryptic and occur at low densities is more difficult because their behavior makes the survey methods used for ungulates ineffective, e.g., assuming perfect detection probability (Miller 1990, Obbard et al. 2010). Historically, many state agencies set harvest limits for carnivores based on harvest data (Hristienko and McDonald 2007), including sex ratio and age structure of the harvested animals, which, along with other analytical approaches, can be used to infer harvest effects on a population (Garshelis 1990). Yet, hunter selectivity and sex-specific vulnerability may influence harvest composition (Miller 1990, Beston and Mace 2012). Thus, additional information provided by abundance and density estimates generated from robust statistical methods can aid in setting harvest limits for black bear populations.

New Mexico's most recent black bear density estimates were derived from a comprehensive, decade-long study on black bear ecology in the 1990s in which researchers estimated study area specific density using population reconstruction (Downing 1980), or backdating, to estimate the minimum population size during the study and then divided that estimate by the effective trapping area (ETA; Costello et al. 2001) to obtain a minimum density estimate. The ETA is an estimate of the actual area used by identified individuals to account for home ranges that straddle the study area boundary and may bias abundance estimates (Dice 1938, Wilson and Anderson 1985). Costello et al. (2001) estimated the ETA using the distribution of live-capture trap sites buffered by the mean activity radius of adult bears. Their minimum density estimate for the more northern, mesic, and presumably more productive Sangre de Cristo Mountains was 17.0 bears/100 km² (310 km² study area) while their estimate for the more southern, xeric, and presumably less productive Mogollon Mountains was 9.4 bears/100 km² (423 km² study area). It is important to note that backdating a population fails to account for undetected individuals or provide measures of uncertainty in estimates, thereby producing only a minimum population estimate. They extrapolated these minimum density estimates to similar black bear habitat throughout New Mexico assigning areas with habitat conditions in between the Sangre de Cristo Mountains and Mogollon Mountains a density equal to the mean of the two minimum density estimates (i.e., 13.2 bears/100 km²). Costello et al. (2001) estimated the statewide minimum population by multiplying minimum density by the area of statewide primary habitat identified through their habitat suitability analysis, which introduces another source of uncertainty that was not quantified. Along with the density estimates, Costello et al. (2001) provided the NMDGF with a population model that incorporated the new density estimates, harvest data, mast survey data, and the relationship between mast production and reproductive success to model abundance and trend of black bear abundance in each Bear Management Zone (BMZ). These model-based abundance estimates, coupled with yearly harvest and mast survey data, have been the basis for establishing black bear harvest limits in New Mexico (Rick Winslow, NMDGF, personal communication). Although live-capture provides a wealth of information on age, dispersal, fecundity, health, home range size, and mortality rates, it

is still inferentially limited due to small sample sizes. While Costello et al. (2001) was a progressive and highly informative study on New Mexico black bears, the capabilities of the technology at that time limited their ability to estimate abundance and density.

Capture-recapture (CR) is a common method for estimating abundance and density of animals and associated parameter uncertainty (Williams et al. 2002). Abundance estimates using CR are determined by comparing the ratio of uniquely marked individuals to unmarked individuals captured each sampling occasion in live capture studies (Pollock et al. 1990). Gould and Kendall (2013) summarize CR methodology and recent advances. Low capture probabilities and sample sizes inherent with species that typically reside at the low densities characteristic of carnivore populations hinders management agencies from utilizing traditional CR techniques for some species (Mills et al. 2000, Settlage et al. 2008). Noninvasive genetic sampling (NGS) revolutionized CR research by providing the ability to use remotely collected DNA samples to identify individuals (Waits and Paetkau 2005). Consequently, NGS enabled researchers to estimate population parameters for carnivores by increasing detection probability, increasing sample size of individuals detected, increasing the size of the study area, decreasing tag loss, and decreasing invasiveness compared to live capture studies (Woods et al. 1999, Mills et al. 2000). However, density estimators using traditional non-spatial CR methods are often less reliable because of the ad hoc and arbitrary estimate of the ETA, which introduces an unquantifiable error (Wilson and Anderson 1985, Parmenter et al. 2003).

Spatially explicit capture-recapture (SECR) models remedy this issue by estimating the number of home range centers within the study area, and subsequently density, directly, using a spatial point process (Efford 2004, Gopalaswamy 2013). By using SECR models, accounting for edge effects has been rooted in statistical theory and incorporated into the modeling process thereby eliminating the need to estimate ETA. Furthermore, integrating the distribution and location of sampling devices into the model eliminates individual heterogeneity related to unequal trap exposure (Borchers 2012). To date, SECR methods have shown improved parameter estimation compared to non-spatial methods with simulated datasets (Ivan et al. 2013, Whittington and Sawaya 2015) and similar or lower density estimates in empirical comparisons (Obbard et al. 2010, Stetz et al. 2014, Whittington and Sawaya 2015), particularly when distance to edge and sampling effort are not included in CR models. Although the accuracy of any density estimate is unknown, use of statistically robust estimation methods yields greater confidence in a management agency's ability to set defensible management objectives that will help ensure the long-term viability of harvested animal populations.

In light of advances in sampling (Woods et al. 1999) and statistical methods (Efford 2004), NMDGF began a collaborative project with the New Mexico Cooperative Fish and Wildlife Research Unit (NMCFWRU) and New Mexico State University (NMSU) to update their density estimates for New Mexico black bear populations. These estimates will then be used by NMDGF to set harvest limits in the respective study areas. Our (NMCFWRU and NMSU) objectives were to estimate the density of black bears ≥ 1 year of age in primary bear habitat within 7 of the 14 BMZs located within the Sangre de Cristo (BMZs 3, 4, and 5), Sandia (BMZ 8), and Sacramento Mountains (BMZs 11, 12, 13), New Mexico. We used non-invasive genetic samples from hair traps and bear rubs in combination with SECR models to estimate density for each study site.

STUDY AREA

We conducted our research in the Sangre de Cristo, Sandia, and Sacramento Mountains, New Mexico constituting 5 study areas: northern (NSC; 6,400 km²) and southern Sangre de Cristo Mountains (SSC; 3,525 km²), Sandia Mountains (300 km²), and northern (NSacs; 925 km²) and southern Sacramento Mountains (SSacs; 2,775 km²). Interstate 25 and Interstate 40 separated the 3-mountain ranges. The sampling area for each study area was limited to primary habitat identified by Costello et al. (2001; Figure 1). Costello et al. (2001) used the New Mexico Gap Analysis land cover map (NMGAP, Thompson et al. 1996) to classify primary habitat as all closed-canopy forest and woodland types. All 5 study areas were managed as multiple-use forests encompassing portions of 4 National Forests (Carson, Cibola, Lincoln, and Santa Fe), 6 wilderness areas (Columbine-Hondo, Latir Peak, Pecos, Sandia Mountain, Wheeler Peak, and White Mountain), and 25 private landowners. Maximum elevation was 4,011 m, 3,254 m, and 3,649 m for the Sangre de Cristo, Sandia, and Sacramento Mountains and minimum elevations were approximately 1,900 m, 1,700 m, and 1,500 m, respectively. The Southern Rocky Mountains floristic district characterizes the Sangre de Cristo Mountains while the Sandia and Sacramento Mountains are characterized by the Mogollon floristic district (McLaughlin 1992). Dominant vegetation types in the study areas include: oak–mountain mahogany (*Quercus* spp. – *Cercocarpus* spp.) scrublands; piñon pine (*Pinus edulis*) - juniper (*Juniperus* spp.) woodlands; ponderosa pine (*P. ponderosa*), white pine (*P. monticola*), Douglas fir (*Pseudotsuga menziesii*), aspen (*Populus tremuloides*), Engleman spruce (*Picea engelmannii*) and subalpine fir (*Abies lasiocarpa*) mixed-forest, and bristlecone (*P. aristata*) and limber (*P. flexilis*) pine forests (Costello et al. 2001). Important mast-producing species include oak, piñon pine, juniper, algerita (*Berberis haematocarpa*), chokecherry (*Prunus virginiana*), gooseberry (*Ribes* spp.), bear corn/squawroot (*Conopholus alpina*), cactus fruits (*Opuntia* spp.) and sumac (*Rhus* spp.; Kaufmann et al. 1998, Costello et al. 2001).

METHODS

Field Sampling

We used hair traps (Woods et al. 1999) and bear rubs (Kendall et al. 2008) concurrently to sample black bear populations (Sawaya et al. 2012, Stetz et al. 2014). We sampled the black bear populations by systematically distributing a grid of 5-km x 5-km cells, with a randomly determined origin, across the landscape. A 5-km x 5-km cell size allowed us to place 4 hair traps within the average fixed kernel female home range in the Sangre de Cristo Mountains (27.6 km²; Costello et al. 2001). We then set hair traps across primary habitat in areas most likely to encounter bears (Figure 2, 3, 4; Costello et al. 2001). We chose trap site locations based on suspected travel routes, occurrence of seasonal forage (e.g., green grass and ripe soft and hard mast), and presence of bear sign. We set hair traps and bear rubs across 4 sampling occasions in the NSC (22 April – 5 September 2012) and SSC (29 April - 9 September 2013) and across 6 sampling occasions in the Sandias, NSacs, and SSacs (5 May – 6 August 2014). Due to logistical constraints, a sampling occasion in the NSC and SSC lasted 4 weeks whereas the sampling occasion for the Sandias, NSacs, and SSacs was 2 weeks.

A hair trap consisted of a single strand of barbed wire wrapped around ≥ 3 trees with a lure pile constructed from woody debris, rocks, pine needles, and leaves at the center (Woods et al. 1999). During each sampling occasion in the NSC and SSC, 1 of 4 non-consumable lures (cow blood/fish emulsion mixture, anise oil, fatty acid scent tablet, or skunk tincture/lanolin

mixture) was randomly selected and applied to the lure pile to attract bears into the enclosure and increase the novelty of hair traps to increase recapture rates. In the Sandias, NSacs, and SSacs we randomly selected and applied 1 of 2 non-consumable lures (cow blood/fish emulsion mixture or skunk tincture/lanolin mixture) each occasion. Based on our judgement in the field, we eliminated anise oil and fatty acid scent tablets because their scent duration and dispersal distance was inferior compared to the other two lures. Therefore, we believe the cow blood/ fish emulsion and skunk tincture/lanolin mixtures provided a better opportunity to attract bears over a longer period of time and greater distance. When a bear passed over or under the wire to investigate the lure pile, a barb snagged a tuft of hair from the individual. We assumed that cubs of the year were too small to be sampled by the barbed wire based on the size of cubs photographed at hair traps by trail cameras. Thus, sub-adults and adults were our sampled population. A sample consisted of all hair caught in one barb, and we used our best judgement to define hair samples collected from the lure pile. We deposited each hair sample in a separate paper coin envelope. We sterilized the barbed wire with a propane torch to ensure we removed any remaining hair to prevent false recaptures during the next sampling occasion. Hair traps were moved (100 m – 2.5 km) each occasion to help increase novelty and recapture rates (Boulanger and McLellan 2001, Boulanger et al. 2004, Boulanger et al. 2008).

Bears rub on trees, power poles, barbed-wire fences, wooden signs, and road signposts (Burst and Pelton 1983, Green and Mattson 2003). We opportunistically identified and collected hair from bear rubs along trails used to navigate to hair traps. We identified bear rubs by evidence of rubbing behavior such as a smoothed surface and snagged hair on the surface (Kendall et al. 2008, 2009). We attached 3-short strands of barbed wire vertically to the rub structure in order to collect discrete, higher quality hair samples (Kendall et al. 2008, 2009, Stetz et al. 2014). Rubs were identified at varying time intervals across sampling occasions, however, once established they were checked concurrently with nearby hair traps. We collected hair samples only from the barbed wire to ensure that the samples collected were from individuals that visited the rub during the sampling occasion and we sterilized the barbed wire to prevent false recaptures (Kendall et al. 2009). All hair samples were stored in an airtight container on silica desiccant at room temperature.

Genetic Analysis

We identified individuals by comparing multilocus genotypes generated for hair samples using 8 polymorphic microsatellite loci (G1D, G10B, G10L, G10M [Paetkau et al. 1995]; G10H, G10J, G10U [Paetkau et al. 1998]; MU59 [Taberlet et al. 1997]). We used the amelogenin or ZFX/ZFY markers to identify the sex of the individual (Paetkau 2003, 2004; Yamamoto et al. 2002; Durin et al. 2007). We selected specific markers for individual identification by ensuring that the mean expected heterozygosity for each marker was between 0.70 and 0.80 (Paetkau 2003, 2004). These markers were determined from an initial subsample from the NSC population in 2012. Because NGS-collected samples may contain low quantity and quality DNA (e.g., hair vs. tissue), genotyping errors may create or delete individuals, which may bias estimates (Mills et al 2000, Lukacs and Burnham 2005). Paetkau (2003) suggested that the largest source of genotyping error resulted from human error when identifying alleles at a locus, which only training and experience could reduce. Therefore, we sent our genetic samples to Wildlife Genetics International (WGI), which is a genetics laboratory that specializes in strict laboratory and error-checking methods that reduce genotyping errors that may arise from poor quality or small quantities of DNA (Paetkau 2003, Kendall et al. 2009). The laboratory has conducted over

2,000 projects including successfully identifying 653 samples without error during a blind sample test (Kendall et al. 2009). Thus, WGI has established a reputation for integrity and high quality work.

First, we eliminated samples that contained insufficient genetic material for analysis (no root, ≤ 1 guard hair, or < 5 underfur hairs) or appeared to be from heterospecifics. Next, we used either the G10J or ZFX/ZFY marker as a prescreen to remove low quality hair samples that were likely to fail during the multilocus genotyping phase. After the prescreen, we amplified the 9 candidate markers for each sample. We eliminated samples that failed to amplify at ≥ 3 loci or that amplified ≥ 3 alleles at 1 marker because they indicated a mixed sample from 2 individuals. We reanalyzed the samples that failed at < 3 loci resulting in either a full 9-locus genotype or a discarded sample. We examined pairs of samples that were mismatched at 1 or 2 markers (1MM pairs or 2MM pairs) for evidence of amplification or human error. We then reamplified and resequenced the mismatched pair for these samples under the assumption that genotyping error may have created the similarity between the two samples (Paetkau 2003). If a 1MM or 2MM pair remained between samples, then we considered the two samples to be from separate individuals, otherwise, we identified and corrected the genotyping error and we concluded that the two samples were from the same individual. We assigned individual ID to each sample with a unique multilocus genotype based upon the first sample to identify the individual's genotype. We calculated the expected and observed heterozygosity for the Sangre de Cristo, Sandia, and Sacramento Mountains using program GENEPOP (Genepop on the Web, Raymond and Rousset, 1995). Detailed laboratory methods may be found in Paetkau (2003, 2004).

Density Estimation

We used genotypes of individual samples to generate capture-recapture encounter histories for each uniquely identified black bear. We then used these capture histories to estimate density using spatially explicit capture-recapture (SECR) models (Efford 2004, Efford et al. 2009a, Efford et al. 2013) with the R package “secr” (Efford 2013). We used SECR to estimate 3 parameters: density (D), detection probability (g_0), and the spatial scale over which the detection probability declines (σ ; Efford et al. 2004). We used a half-normal detection function for our observation model, which represents the probability of detecting an individual as a function of the individual's home range location relative to the detection device (Efford et al. 2009a). We then specified a homogeneous Poisson distribution as our state model to represent the spatial distribution of animals across the sampling grid. We only included primary habitat as identified by Costello et al. (2001) for black bears in New Mexico for our habitat mask. The habitat mask identifies the area of habitat/non-habitat within and buffered around the trapping grid. We estimated the state space (i.e., the trapping grid and all individuals potentially exposed to capture outside the trapping grid) using the secr function suggest.buffer for each study area. However, this buffer is not to be confused with the ad hoc method of identifying a buffer using the ETA. Instead, the suggested buffer is the area of integration and includes all animals with a non-zero probability of detection (Ivan et al. 2013). Habitat may extend beyond the mask but individuals outside the buffer have a negligible probability of encounter (Borchers and Efford 2008, Royle et al. 2014). Derived from the capture data using suggest.buffer, we set the habitat mask buffer for the NSC, SSC, Sandias, NSacs, and SSacs as 18.75 km, 25.40 km, 13.23 km, 14.84 km, and 11.03 km, respectively. Variability in sampling effort may negatively bias density estimates and reduce the ability to explain variation in detection probability (Efford et al. 2013). We accounted

for variable sampling effort by using the number of days each hair trap and bear rub was active (Kendall et al 2009, Sawaya et al 2012, Efford et al. 2013).

We tested for variation due to time (t), sex, elevation (elev), detector type (type; hair trap versus bear rub), and land cover classification (veg) as predictors of g_0 , and σ . Elevation was standardized prior to analyses by subtracting the mean and dividing by the standard deviation (Gelman and Hill 2007). We did not consider behavioral models because we did not provide a food reward. We modeled D only using sex because we did not expect bear density to vary by time, land cover type, or elevation. We entered sex into our models as a session covariate. We modeled g_0 and σ concurrently by fitting 4 models that varied by time, sex, land cover type, and elevation. We also included models that varied by temporal variation for g_0 and land cover for σ , temporal variation for g_0 and elevation for σ , land cover for g_0 and temporal variation for σ , and elevation for g_0 and temporal variation for σ . We chose temporal variation and sex as covariates because multiple studies have reported that detection probability and movement patterns fluctuate over the course of the sampling period and differ between males and females (Kendall et al. 2009, Sawaya et al. 2012, Stetz et al. 2014, Ciucci et al. 2015). We selected elevation and land cover to represent the spatial heterogeneity of food resources exploited by black bears. We hypothesized that this heterogeneity could influence g_0 and σ depending on the presence or absence and distribution of food on the landscape. However, we did not include both land cover type and elevation in the same model due to concerns of multicollinearity. We also constructed models with temporal variation for g_0 and σ in addition to additive variation with either elevation or land cover. We included additive effects because we hypothesized that g_0 and σ are likely to vary because of the black bear mating season, hyperphagic foraging behavior during late summer and early fall, and the temporally variable distribution of food resources on the landscape.

We extracted the elevation for each detector using the National Elevation Dataset 30 m resolution digital elevation model. We extracted land cover using the Interagency Landfire Project (www.landfire.gov; Rollins 2009) land cover classification at 30 m spatial resolution. We combined 6 Landfire land cover classifications into 5 categories: aspen – conifer, mixed conifer (combination of Douglas fir and white pine), piñon pine – juniper, ponderosa pine, and spruce – fir. Variability in abundance and distribution of each land cover classification across study areas resulted in a different number of categories and, consequently, number of parameters in each model among study areas. Aspen-conifer and spruce-fir were only included in the NSC and SSC. Mixed-conifer was included in all study areas except the Sandia Mountains. Piñon-juniper and ponderosa pine were included in all study areas. We extracted elevation and assigned the dominant land cover classification surrounding the location of each detector using ArcGIS 10.2.1 (Environmental Systems Research Institute, Inc. [ESRI], Redlands, California, USA). Each model serves as a hypothesis modeling the heterogeneity in the data for each estimable parameter. We used Akaike's Information Criterion corrected for small sample size (AIC_c) to rank our final model set (Akaike 1973, Hurvich and Tsai 1989). We used the difference in AIC_c score (ΔAIC_c) between the top-ranked model and competing models to compare relative support, and we provide the AIC_c weights (w_i) to show the proportional support for each model (Burnham and Anderson 2002). We used model averaging to account for model selection uncertainty when the top ranked model in the final model set garnered less than 0.90 of the model weight (Burnham and Anderson 2002).

We conducted our study with authorization under Convention on International Trade in Endangered Species Export Permits 12US86417A/9, 13US19950B/9, and 14US43944B/9, and New Mexico Department of Game and Fish Authorization for Taking Protected Wildlife for Scientific and/or Education Purposes Permit 3504. All procedures were approved by the New Mexico State University Institutional Animal Care and Use Committee (Protocol number 2011-027).

RESULTS

Field Sampling

We set 557 hair traps that were open for 57,010 trap days and we collected 3,825 hair samples. In addition, we identified and sampled 112 bear rubs, which yielded 258 hair samples over 7,007 trap days (Figure 2, 3, and 4; Tables 1 and 2). Sampling effort varied across study areas and was dependent on the number of hair traps and bear rubs set, the length of a sampling occasion for each study area (4 weeks vs. 2 weeks), and the accessibility of areas due to stochastic weather events and wildfire. The number of hair traps that collected ≥ 1 hair sample ranged from 28% to 42% with most traps collecting a hair sample in 1 – 2 sampling occasions. The number of hair samples collected during a particular occasion increased over the course of the summer and decreased towards the conclusion of sampling with peak collection during June and July (Table 2).

Genetic Analysis

The mean observed heterozygosity for our suite of genetic markers was 0.73 (Table 3). The number of individuals that were mismatched at 1 or 2 markers was extremely low with 3, 0, 0, and 0 observed 1MM-pairs and 0, 4, 0, and 4 observed 2MM-pairs and 3, 0, 0, and 0 for the NSC, SSC, Sandias, and Sacramento Mountains, respectively. Excluding the NSC, the observed mismatched pairs fell within the expected mismatch distribution for each population (Paetkau 2003). The deviation from expectation observed in the NSC was likely due to chance (D. Paetkau, WGI, personal communication). From the 4,083 total hair samples collected, we eliminated 27.7% from the genotyping process. Reasons for excluding hair samples included: the sample contained insufficient genetic material for analysis (26.1%), was not of black bear origin (1.49%), or contained DNA from more than one individual (0.17%). We attempted to genotype 2,950 (72.3%) hair samples but were only able to generate a full 9-loci genotype for 49.6% of the eligible samples and identified 726 (368 M: 358 F) individuals (Table 4). The observed sex ratio for each study area was approximately equal. Genotyping success varied across study areas (43% - 60%), but overall, our success rates were lower than the 75% success rate observed in similar studies (D. Paetkau, WGI, personal communication). Contrary to our prediction, when we shortened the length of the sampling occasion from 4 weeks (NSC and SSC) to 2 weeks (Sandias, NSacs, and SSacs), we increased the percentage of successful genotypes by 4%.

Density Estimation

We detected the majority (61% – 85%) of individuals in each study area only once with similar average number of detections of males (1.19 – 1.67) and females (1.14 – 1.56; Table 5). The number of unique individuals detected during each occasion for the NSC, NSacs, and SSacs increased over the course of sampling, peaking mid-summer, and subsequently decreasing towards the end of the season (Figure 5); this pattern was similar to the total number of hair

samples collected per sampling occasion (Table 3). However, the number of unique individuals detected continued to increase over the course of the summer reaching its highest point during the last sampling occasion for both the SSC and the Sandias. Mean maximum recapture distance for males ranged from 4.23 to 12.46 km with a maximum distance of 52 km by one individual in the NSC ($n = 3 - 33$). Mean maximum recapture distance for females ranged from 0.38 to 4.59 km with a maximum distance of 47 km by one individual, also in the NSC ($n = 4 - 23$; Table 5). Three individuals were detected in two study areas. The first two detections were males we detected in the NSC in 2012 and then again in the SSC in 2013, and the third was a female we detected in the SSC in 2013 and then again 90 km away in the Sandias in 2014.

The most supported model for the NSC received all model weight and suggested that time and land cover type were important covariates explaining both g_0 and σ (Table 6). The top model ($w_i = 0.87$) for the SSC included time and elevation, whereas the second highest-ranking model ($w_i = 0.13$) included time and land cover type (Table 7). The top model ($w_i = 0.96$) for the Sandias indicated that both g_0 and σ varied by sex (Table 8). The highest-ranking model ($w_i = 0.96$) for the NSacs included time and land cover type for both g_0 and σ (Table 9). There was higher model selection uncertainty for the SSacs than any other site, but the most supported model ($w_i = 0.50$) included land cover type for both g_0 and σ (Table 10). The second and third ranked models included time and land cover, and time and elevation, respectively; these three top-ranked models contained all of the model weight (Table 15). For the NSC, we were able to fit all models except when g_0 and σ were modeled concurrently with elevation (i.e., $g_0 \sim \text{elev}$, $\sigma \sim \text{elev}$), concurrently with time and elevation (i.e., $g_0 \sim t + \text{elev}$, $\sigma \sim t + \text{elev}$), independently with elevation (i.e., either $g_0 \sim \text{elev}$, $\sigma \sim \text{constant}$; or $g_0 \sim \text{constant}$, $\sigma \sim \text{elev}$), independently with time and elevation (i.e., either $g_0 \sim t + \text{elev}$, $\sigma \sim \text{constant}$; or $g_0 \sim \text{constant}$, $\sigma \sim t + \text{elev}$), and with time and elevation for different parameters (i.e., either $g_0 \sim t$, $\sigma \sim \text{elev}$; or $g_0 \sim \text{elev}$, $\sigma \sim t$) because of computational limitations. For the NSacs, we did not fit a model using detector type to predict g_0 and σ concurrently because only one bear rub was set.

Detection probability (g_0) was highest for the Sandias ($g_0 = 0.02$), but overall, g_0 was low across all study areas (Table 11). The final model for all study areas, except the Sandias, did not support a sex effect. Despite having the highest g_0 relative to the other study areas, the precision of the Sandias density estimate was the lowest; whereas, the NSC density estimate was the most precise despite a low g_0 (Table 11). Mean density estimates varied within and between mountain ranges (range 16.55 to 21.86 bears/100 km²) and were model averaged for the SSC and SSacs (Table 11).

DISCUSSION

Our study provided the most current density estimates for multiple New Mexico black bear populations in over a decade (Costello et al. 2001). Our results suggest that densities are similar (SSacs) to or higher (NSC, SSC, Sandia, and NSacs) than the previous estimates used by NMDGF (17 bears/100 km² and 13.2 bears/100 km²) to manage New Mexico black bear populations. The differences in estimated density could be a result of an increasing black bear population, simple variation in population density due to time, a difference in the state of environmental conditions, or different sampling and analytical methods. For example, Costello et al. (2001) did not account for uncollared individuals in their density estimation approach and thus likely underestimated the density of the population by not accounting for imperfect detection. Furthermore, their abundance and density estimates provided no measure of

uncertainty because their estimation technique was not statistically based and did not provide a measure of uncertainty. As a result, Costello et al. (2001) used minimum abundance to derive their density estimates, which may explain at least some of the difference in our density estimates given we estimated mean density. Regardless, unless populations are extremely stable, we would expect density of a population to vary across space and with time.

The relative importance of the covariates we selected for modeling parameters was similar across study areas. The top model for all study areas held density constant suggesting an equal sex ratio in each population. Time of the detection event and the land cover type or elevation at which the detector was deployed were helpful covariates in modeling heterogeneity in both g_0 and σ for all study areas except the Sandia Mountains, which included sex of the individual detected as an important explanatory variable. The importance of temporal variability is likely a result of seasonal reproductive and foraging behaviors (Alt et al. 1980, Garshelis and Pelton 1981, Costello et al. 2003). Black bear mating season begins with den emergence, which can be as early as late March, peaks in June, and typically ends by July (Costello et al. 2001). During this period, males move more as they traverse their home range searching for receptive females (Young and Ruff 1982, Costello 2008, Lewis and Rachlow 2011). Mast season begins in July, with peak masting occurring during late summer and early fall (Costello 2008). At this time, bears begin to enter a hyperphagic state when they increase daily caloric intake from 8,000 kcal to 15,000 – 20,000 kcal to build up fat stores for hibernation and reproduction in females (Nelson et al. 1980). Bear home range size and distance between sequentially recorded movements increases as bears travel outside their core area to exploit the spatially and temporally variable mast (Ostfeld et al. 1996, Costello 2008), which is an important food source and highly correlated with black bear reproductive output in New Mexico (Costello et al. 2003). Increased movement rates and enlarged home range size during mating and hyperphagia would likely affect trap exposure rates on the landscape, thus affecting g_0 and σ .

The influence of land cover and elevation is likely a function of black bears responding to spatio-temporal changes in food abundance (Costello and Sage 1994, Costello et al. 2001, Mazur et al. 2013, McCall et al. 2013). Using scat surveys, Costello et al. (2001) reported that grasses, forbs, and ants tend to dominate bear diets during the pre-mast season (den emergence – 20 July). As the summer progresses, early mast season (21 July – 15 September) diets included soft mast species including chokecherry, squawroot (*Conopholis alpina*), and gooseberry as well as acorns (56% of scat volume). Diets during the late mast season (15 September – den entrance) are dominated by acorns (87% of scat volume) and supplemented with juniper berries (Costello et al. 2001). Mid-elevation land cover types (i.e., mixed conifer) are likely to contain a higher abundance of pre-mast species (grass and forbs) due to earlier snowmelt (compared to higher elevations) and moist conditions near riparian areas compared to dry, lower elevations. As snow melts, grasses and forbs will increase in abundance and distribution. With the arrival of monsoonal rains, soft mast will begin to ripen at lower elevations. Once oak acorns ripen in late summer/early fall, black bears begin to shift their attention towards vegetation types containing abundant acorns.

The main challenge we faced was genetic samples failing to produce a reliable genotype (i.e., not generating an individual ID for a particular hair sample). The inability to assign a reliable genotype to half of our genetic samples (44% - 61%) reduced the number of unique individuals and spatial recaptures (i.e., recapture of individuals at different traps) available for analysis. Consequently, this led to low detection probability and likely affected estimation of σ

inducing larger standard errors and less precise density estimates (Efford et al. 2004, Sollmann et al. 2012, Sun et al. 2014). The relatively more precise NSC density estimate, despite a low g_0 , may be a result of a greater number of unique individuals and recaptures, which provided sufficient data for the model to predict unobserved movement distances (Table 5; Sollmann et al. 2012, Sun et al. 2014). Interestingly, despite having the highest estimated g_0 among all study areas, the density estimate for the Sandias was the least precise, which may have been influenced by a low number of recaptures for both sexes, a low g_0 for males, a large individual heterogeneity in male movement patterns, and/or an over-partitioning in data due to estimating sex specific detection parameters (i.e., g_0 and σ). However, we believe the greatest factor affecting the density estimate is the number of individuals detected. Detecting fewer individuals results in less data to estimate the model parameters. Consequently, small sample size coupled with few recaptures can result in wider confidence intervals (Sun et al. 2014), which is likely the case for the Sandia density estimate. Our second highest-ranking model for the Sandias estimated density as 18.4 bears/100 km², which is still higher than the current density estimate used to manage the population (13.2 bears/100 km²). Replicative sampling may help provide more information on the density of the Sandias.

In the SSC, we likely lost hair samples due to two forest fires, the Tres Lagunas and Jaroso Fires (Figure 6). The Tres Lagunas Fire started 30 May 2013 and burned 4,135 ha just below the southern boundary of the Pecos Wilderness. The Jaroso Fire started 10 June 2013 and burned 4,511 ha in the northwest corner of the Pecos Wilderness. We suspect these fires contributed to a less precise density estimate for the SSC. These fires affected 450 km² (12.7%) of the trapping grid and prevented us from checking hair traps located in close proximity to the fire primarily during the second and third sampling occasions (3–13% of total hair traps). Moreover, many of the fire-affected traps were in relatively high quality bear habitat where we would expect higher bear abundance. Anecdotally, post-fire these hair traps consistently yielded more hair samples than hair traps located in some areas that were unaffected by the fires. The inability to collect samples in this area may have reduced the number of new individuals detected, and, more importantly, most likely reduced the number of recaptures necessary for more precise parameter estimates. The limited access also prevented us from identifying more bear rubs across the SSC, restricting our ability to utilize multiple sampling methods and hindering our ability to minimize the impacts of capture heterogeneity (e.g., age, sex, reproductive status) caused by any one survey method (Boulanger et al. 2008). The use of hair traps and bears rubs concurrently has also been shown to increase the precision of parameter estimates compared to those generated by hair traps alone (Sawaya et al. 2012, Stetz et al. 2014), and likely aided our ability to generate more precise density estimates given our low amplification rates. We also hypothesize that the presence of fire on the landscape increased movements of individuals (Cunningham and Ballard 2004) as seen by our estimate of σ for the SSC, which is 3x – 24x larger than the other study areas.

Overall, a net loss in sampling occasions and hair samples reduced the amount of data available for the SSC analysis. The few individuals we recaptured in each occasion and the large number of unique bears identified in the last occasion, after the fires were extinguished or contained, support our argument that the fires in the SSC affected our model parameter estimates. Ideally, as a population is sampled the number of unique individuals captured declines

over time (i.e., fewer unmarked individuals are encountered). Yet, in the SSC we captured 34% of all unique individuals during the last sampling occasion. While the number of individuals detected the last occasion in the NSC is still high (20%), it seems that the fires in the SSC influenced our ability to detect bears in this area as compared to the NSacs and SSacs (both 10%; Figure 5). Limited access to these hair traps during the fires led to longer sampling occasions and greater exposure to environmental conditions (i.e., exposure increased from 4 weeks to ≥ 8 weeks), subjecting hair samples to longer periods of environmental exposure, particularly to ultraviolet radiation (UV).

We suspect that for all study areas UV radiation is the main factor explaining failure of hair samples to produce a complete genotype (Stetz et al. 2015). Ultraviolet radiation causes DNA degradation by the formation of chemical compounds known as dimers. Dimers form by the binding of two adjacent, pyrimidine-nucleotide bases (cytosine and thymine) on a single strand of the double helix instead of binding between cross-strand partners (Jagger 1985). This fusion forms a bulge in the chemical structure of the DNA preventing DNA polymerase from progressing past the dimer and correctly duplicating the sequence, which prevents further amplification of the DNA molecule resulting in an incomplete genotype. Consequently, we suspect that the inability to assign an identity to a large portion of the genetic samples may have reduced the number of unique individuals and recaptures across all study areas. Multiple factors influence UV levels and, subsequently, its effects on DNA degradation including cloud cover, elevation, latitude, time of day, time of year, length of exposure, season, ozone depletion, and atmospheric turbidity (Piazena 1996, Stetz et al. 2015). For example, UV radiation increases with decreasing cloud cover, increases with elevation (9.0% – 11.0% per 1,000 m), and increases with lower latitude (Blumthaler et al. 1997). New Mexico receives substantial amounts of sunshine (Albuquerque 76% vs. U.S 58% average annual possible sunshine; NOAA 2004), is relatively high in elevation (1,200 m – 4,000 m), and is at a lower latitude than other geographic areas where NGS methods have been used to estimate bear abundance and density. Collectively, these factors result in UV radiation levels across much of New Mexico being higher than across most of the U.S. Further, we would expect UV radiation levels to be 1% – 26% higher in our study areas compared to those for Albuquerque, NM (Figure 7; NOAA 2015) because our study areas were typically located at higher elevations. Reducing sampling interval length should increase genotyping success, however, when we reduced our sampling interval from 4 to 2 weeks (which is a common time frame used by similar NGS studies), in the Sandias, NSacs, and SSacs we observed only a marginal improvement in genotyping success (4%). Surprisingly, the lowest genotyping success rate was in the SSacs (44%) given sampling occasions in the SSacs were 2 weeks shorter than the NSC and SSC. Thus, we suggest researchers consider conducting a pilot study to determine the optimal sampling interval for reducing UV degradation of DNA within hair samples particularly for study areas in the southwestern U.S.

Despite these sampling difficulties, we were able to produce density estimates with comparable levels of precision as those obtained in black bear studies conducted elsewhere in the U.S. (Table 12). We believe these estimates were possible due to the large extent of our study areas, which allowed us to detect a larger proportion of the population within each mountain range, increased the potential number of recaptures, and buffered the data from the low

amplification success rates. In addition, we believe because there was no observable spatial pattern in the collection locations of samples that failed to amplify we were still able to gather an adequate representation of movement of individuals on the landscape due to our sampling intensity and use of multiple survey methods. This allowed us to model unobserved movement distances (Sollmann et al. 2012). However, a small data set affected the Sandias estimate resulting in larger confidence intervals than the other study areas, particularly the NSC. It is likely that precision for these two study areas was influenced by the number of individuals detected (NSC: $n = 379$ vs. Sandias: $n = 18$).

Black bears are naturally difficult to sample due to their cryptic behavior and large home ranges. Furthermore, spatially and temporally stochastic environmental (e.g., mast oak and wildfire; Cunningham et al. 2003, Mazur et al. 2013) and anthropogenic (e.g., recreation and roads; Boyle and Samson 1985, Kasworm and Manley 1988) factors confound black bear detection by influencing the distribution of individuals across the landscape. In New Mexico, the abundance and distribution of mast oak heavily influences black bear fitness and movement patterns as they accrue adequate fat reserves for hibernation and reproduction for females (Costello et al. 2001, Costello et al. 2003, Inman et al. 2007). Under the assumption of a count index, multiple years of low black bear harvest may indicate a declining population while multiple years of high black bear harvest may indicate an increasing population. While observed harvest numbers may be a function of a changing population, the observed changes in harvest could be a product of various factors unrelated to the number of animals harvested. In years with average or above average precipitation levels, acorn and soft mast abundance increases. During these times, black bear movement rates are smaller due to the high availability of food on the landscape. Smaller movement rates reduce black bear exposure to hunters resulting in hunters observing, and subsequently, harvesting fewer individuals (Costello et al. 2001, Fieberg et al. 2010). However, when food crops fail, particularly acorn crops, black bear home range size increases, along with hunter harvest rates, due to the increased movements of black bears searching for food (Costello et al. 2001, Fieberg et al. 2010).

In developing sampling designs for future SECR-based black bear density estimation projects, there are multiple considerations. First, the spatial extent of the population must be determined (Sun et al. 2014). Sollmann et al. (2012) suggested that trapping arrays could be smaller than an average male home range but 1.5x larger than the average female home range. Yet, they cautioned that a small trapping array might not provide an accurate representation of movement patterns necessary to inform σ . A larger trapping array may buffer against stochastic environmental events (e.g., mast crop failure) which may cause individuals to move larger distances (McCall et al. 2013). If trapping arrays are large, there is a reduced chance that individuals will move off of the study area and thus not be detected. Selecting study area boundaries is an important aspect to consider when trying to avoid violating geographic closure of the study area. The spacing between hair traps will also influence the spatial extent of the trapping array. Non-spatial CR literature has suggested a trapping density of 4 traps per individual home range, which we adhered to, however, recent simulation work has suggested only 2 hair traps per individual home range may be required when using SECR models (Sollmann et al. 2012, Sun et al. 2014). We stress that an accurate representation of the smallest average home range size is necessary to prevent traps from being spaced too far apart. When traps are spaced too widely, the number of unique individuals and recaptures declines causing a decrease in the precision of the parameter estimates (Sun et al. 2014). If hair traps can be spaced

closer together, then a regular trapping array configuration may be used, however, if they cannot, then a cluster configuration may be preferred with clusters wider than the spacing between hair traps (Sun et al. 2014). Use of fewer traps has the benefit of decreasing the trapping array size, reducing the sampling occasion length reducing environmental exposure, or reducing the number of technicians required for the study potentially saving both time and money. However, depending on the extent of the population, the size of the study area, and available resources it may not be possible to sample all available black bear habitat. In that case, it may be more appropriate to distribute multiple, smaller trapping arrays randomly across the available sampling area instead of one large array (Wilton et al. 2014).

We suggest that future efforts to estimate the density of black bear populations in New Mexico may need to shorten the length of the sampling occasion to reduce DNA degradation via UV radiation, which will increase microsatellite amplification success helping to reduce genotyping errors and increase the number of individual genotypes identified (Stetz et al. 2015). When we decreased sampling occasion length from 4 weeks to 2 weeks the genotype success rate increased by only 4% (Sandia and Sacramento Mountains: 52% vs. SSC: 48%). Thus, a pilot study may be useful to determine the length of time hair samples can remain in the field prior to collection. In addition, researchers may consider setting hair traps and bear rubs in more shaded areas (e.g., north facing slopes) to help reduce exposure to UV radiation. This may help increase the amplification success for hair samples. Increasing the number of personnel would be preferable over fewer hair traps because it would allow for a larger study area or a denser trapping array to be sampled, which should increase detection of long-range movements helping to inform σ , increase recapture rates, and increase the precision of parameter estimates (Sollmann et al. 2012). A larger study area will also place density estimates at the spatial scale at which state agencies make management decisions (Dreher et al. 2007). Personnel should be able to check and reset, on average, 3 – 5 hair traps per day depending on road density. For example, we were able to check more traps in the Sacramento Mountains ($n = 148$) than the SSC ($n = 141$) in half the time (2 weeks vs. 4 weeks, respectively) due to the higher road density in the Sacramento Mountains. Increased seasonal personnel will certainly increase cost, but this cost will be offset by a reduction in total sampling time per season. The other option is to reduce the number of hair traps resulting in a smaller study area or an increased distance between hair traps. A small study area, relative to home range size, will increase the probability that individuals travel off the sampling grid and are unavailable for capture. Individuals will also be unavailable for capture when traps are widely spaced relative to home range size causing some home ranges to fall in between hair traps. Both scenarios will reduce the number of unique individuals identified, the number of recaptures, and ultimately the precision of the parameter estimates (Sollmann et al. 2012, Sun et al. 2014). Careful consideration of these factors must be taken into account when reducing the number of hair traps to ensure a reasonable tradeoff between study area size and the distance between hair traps.

To estimate density, we used SECR models. The SECR analysis may be performed using inverse prediction (Efford 2004), maximum likelihood (ML; Borchers and Efford 2008), or Bayesian based methods (Royle et al. 2009). Inverse prediction was the original constitution of SECR models, but it is applied only to single catch traps (e.g. Sherman-live traps), due to the lack of a ML based single-catch model. Inverse prediction is limited in regards to model selection and the inclusion of parameter covariates (Borchers and Efford 2008). The two prominent statistical paradigms in SECR-based analyses are ML and Bayesian with both

methods providing similar density estimates (Borchers and Efford 2008, Royle et al. 2009). The ML framework is advantageous because these models require less computation time compared to Bayesian methods (Noss et al. 2012). Although, we note that larger study areas and finer discretization increases the necessary computation time for a model. Maximum likelihood methods may require less user knowledge compared to the Bayesian because the latter requires a prior distribution be specified and “model warnings” are often prompted if an error has occurred during model fitting (Noss et al. 2012, Efford 2013). However, users should evaluate model output carefully regardless of statistical paradigm chosen. Bayesian models may be preferred in cases where data sets with small sample size are expected (Noss et al. 2012) because ML models rely on asymptotic theory, which requires larger sample sizes in order to approach normality (Gerber and Parmenter 2015). Model output generated by a Bayesian approach may be difficult to decipher due to the mechanisms of the analysis. To interpret model output, a researcher must be able to understand the influence of model priors, the distribution of the MCMC chains, the posterior model output, and other results generated by the model (Noss et al. 2012). Inverse prediction and ML based SECR models may be fitted in either program DENSITY, which offers a Graphical User Interface (GUI), or the R package “secr” (Efford et al. 2004, Efford 2013). The secr package allows a wider range of analyses including modeling density surfaces and telemetry-integrated capture-recapture, and it provides the user greater flexibility in model optimization and processing. Bayesian estimation may be conducted in either program SPACECAP (Gopalaswamy et al. 2012), which offers a GUI, or in Program R using JAGS (Just Another Gibbs Sampler) in the BUGS (Bayesian inference Using Gibbs Sampling) language (Royle et al. 2014). For our study, we chose to estimate density using the ML based approach because the statistical knowledge and expertise of our research laboratory is rooted in ML theory.

In conclusion, we estimated the density of black bears in 5 study areas within 3 mountains ranges of New Mexico. Our estimates will aid the NMDGF in setting sustainable harvest limits. In addition to density estimates, information on demographic rates (e.g., survival rates and reproduction) and the potential effects that climate change and future land use may have on the demography of black bears may also help inform management of black bears in New Mexico, and may be considered as future areas for research.

ACKNOWLEDGMENTS

We thank our technicians and volunteers for their unwavering dedication even through less than perfect weather conditions and equipment issues: Steve Allen, Casey Barela, Drew Carter, Kerry Cobb, Billy Dooling, Jason Larson, Will Lubenau, Tim Melham, Clay Morrow, Andy Orlando, Shelby Stroik, Trey Turnbull, and the Sandia Mountain Bear Collaborative. Also, many thanks to Lief Ahlm, Nicole Carrier, Les Dhaseleer, Gus Holm, Sarah Holms, Sarah Markert, Pat McGrew, and Bob Welch from Vermejo Park Ranch and Aaron Cook from Eastern New Mexico State University for their sampling efforts. We thank the following private landowners who graciously provided access to their property: Angel Fire Resort, Atmore Express Ranch, Buena Vista Ranch, C.S. Cattle Company, Chase Ranch, Dawson Ranch, Endless Blue Resort, Flying Horse Ranch, Fort Union, Gary Bates, G-F Ranch, I-X Ranch, Jeannie Blattmon, National Rifle Association – Whittington Center, Ojo Feliz Ranch, Pecos River Ranch, Perry Ranch Inc., Philmont Scout Ranch, Rio Costilla Cooperative Livestock

Association, Sandia Pueblo Bobcat Ranch, Torres Ranch, Wheaton Creek Ranch, Ute Creek Ranch, UU Bar Express Ranch, Vista del Valle Ranch, and Vermejo Park Ranch.

We are grateful for the dedication and support from NMDGF biologists and conservation officers Curtis Coburn, Elise Goldstein, Kyle Jackson, Ty Jackson, Jason Kline, Stewart Liley, Chris Neary, Ryan McBee, Eric Nelson, Marcelino Peralta, Ryan Walker, Logan Vanlandingham, and Rick Winslow. Also, thank you to Larry Cordova, Francisco Cortez, Sarah Naegle, Esther Nelson, Mary Orr, and Todd Rawlinson from the U.S. Forest Service for their logistical help. We are indebted to the numerous federal and state agencies and private entities that provided invaluable in-kind and logistical support: Kit Carson Electric Cooperative Inc., Mora-San Miguel Electric Cooperative Inc., NMDGF regional offices, Otero County Electric Cooperative Inc., U.S. Bureau of Land Management, and the U.S. Forest Service – Carson, Lincoln, and Santa Fe National Forest offices.

Our project would not have been successful without the technical expertise provided by Jeff Stetz and Wayne Simoneau, the invaluable knowledge Phil Howes and Huey Ley bestowed in regards to the Pecos Wilderness, and the hospitality provided by the Smith Family as well as Roger Smith and staff at CTG. Many thanks to the folks at Caviness Beef Packers for supplying lure. We would like to thank Chuck Kennedy and the Mountain View Regional Medical Center staff for saving saline bottles, which served as containers for our putrid smelling lure. We thank the New Mexico Chapter of The Wildlife Society and New Mexico State University for scholarship support. The New Mexico Department of Game and Fish, the New Mexico State University Fish, Wildlife, and Conservation Ecology Department, the New Mexico State University Agricultural Experiment Station, the United States Geological Survey-New Mexico Cooperative Fish and Wildlife Research Unit, Vermejo Park Ranch, and T & E Inc provided funding and support. Thank you to Tabitha Graves and Michael Sawaya for reviewing an earlier draft of this report. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

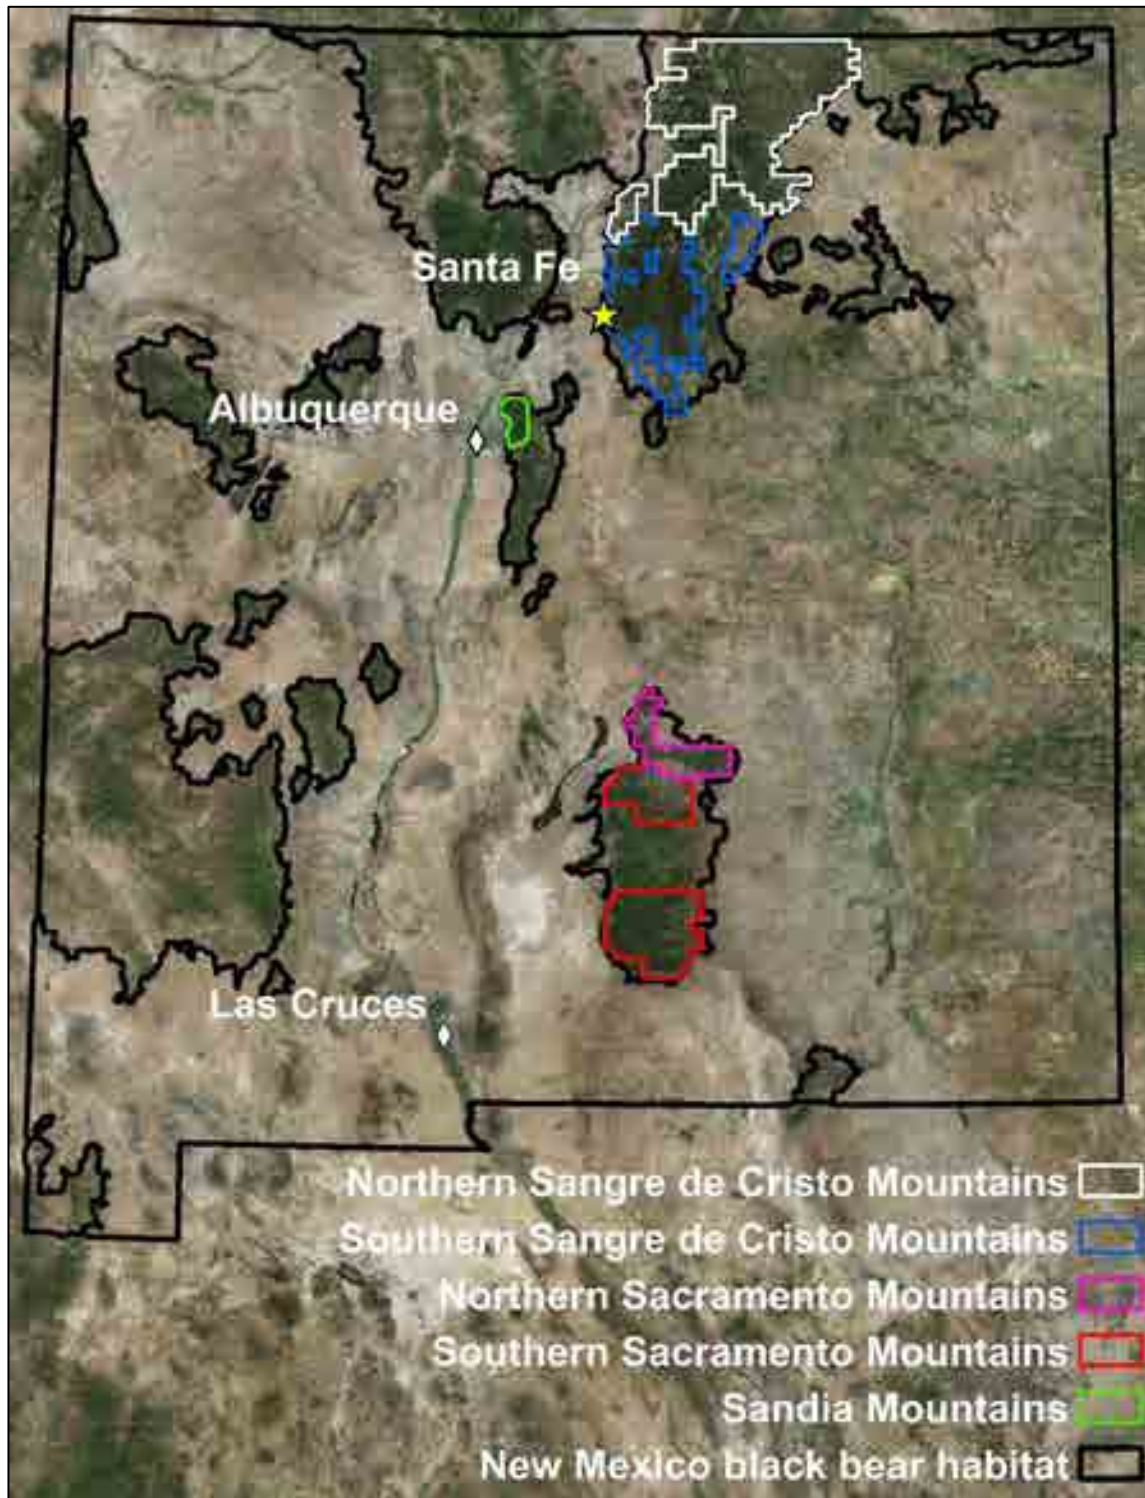

Figure 1. Aerial imagery of black bear habitat in New Mexico highlighting the study areas located within the Sangre de Cristo Mountains, Sandia Mountains, and Sacramento Mountains.

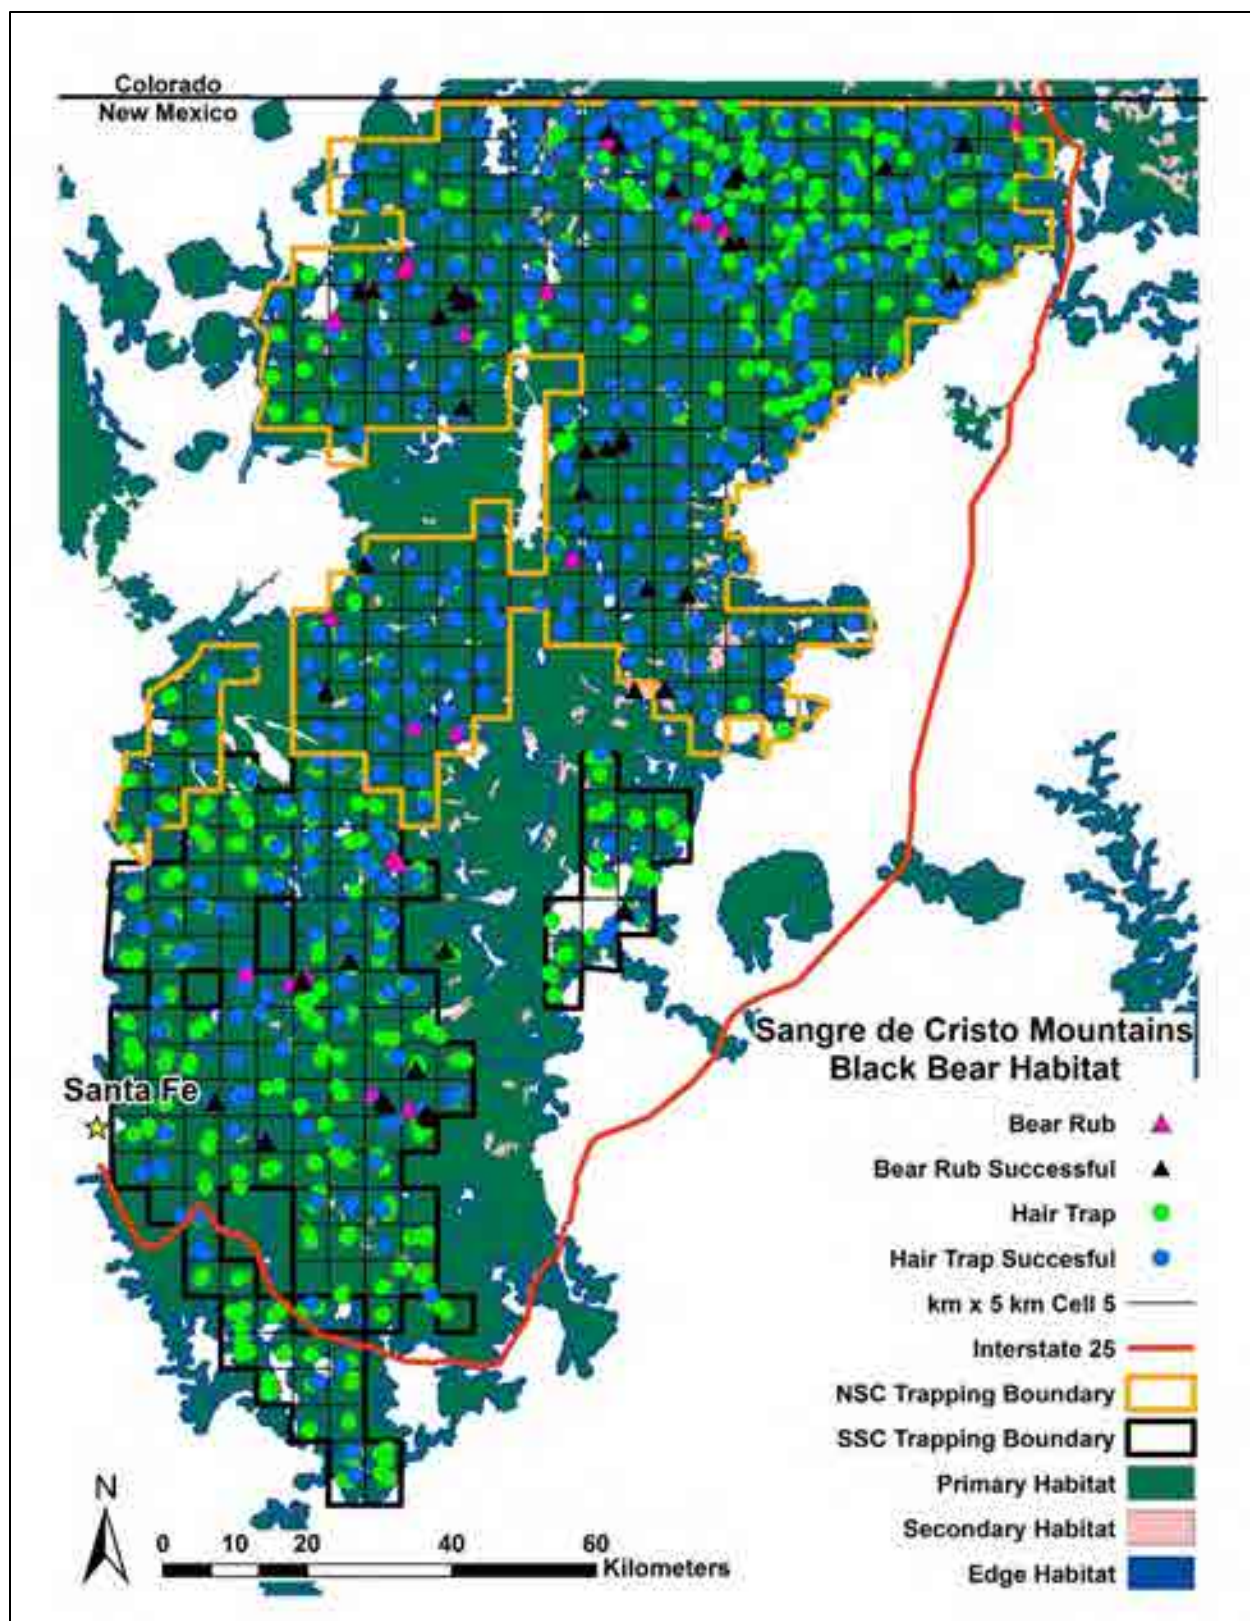

Figure 2. Black bear habitat identified by Costello et al. (2001) overlaid with hair traps and bear rubs set for the northern Sangre de Cristo Mountains, NM in 2012 and 2013.

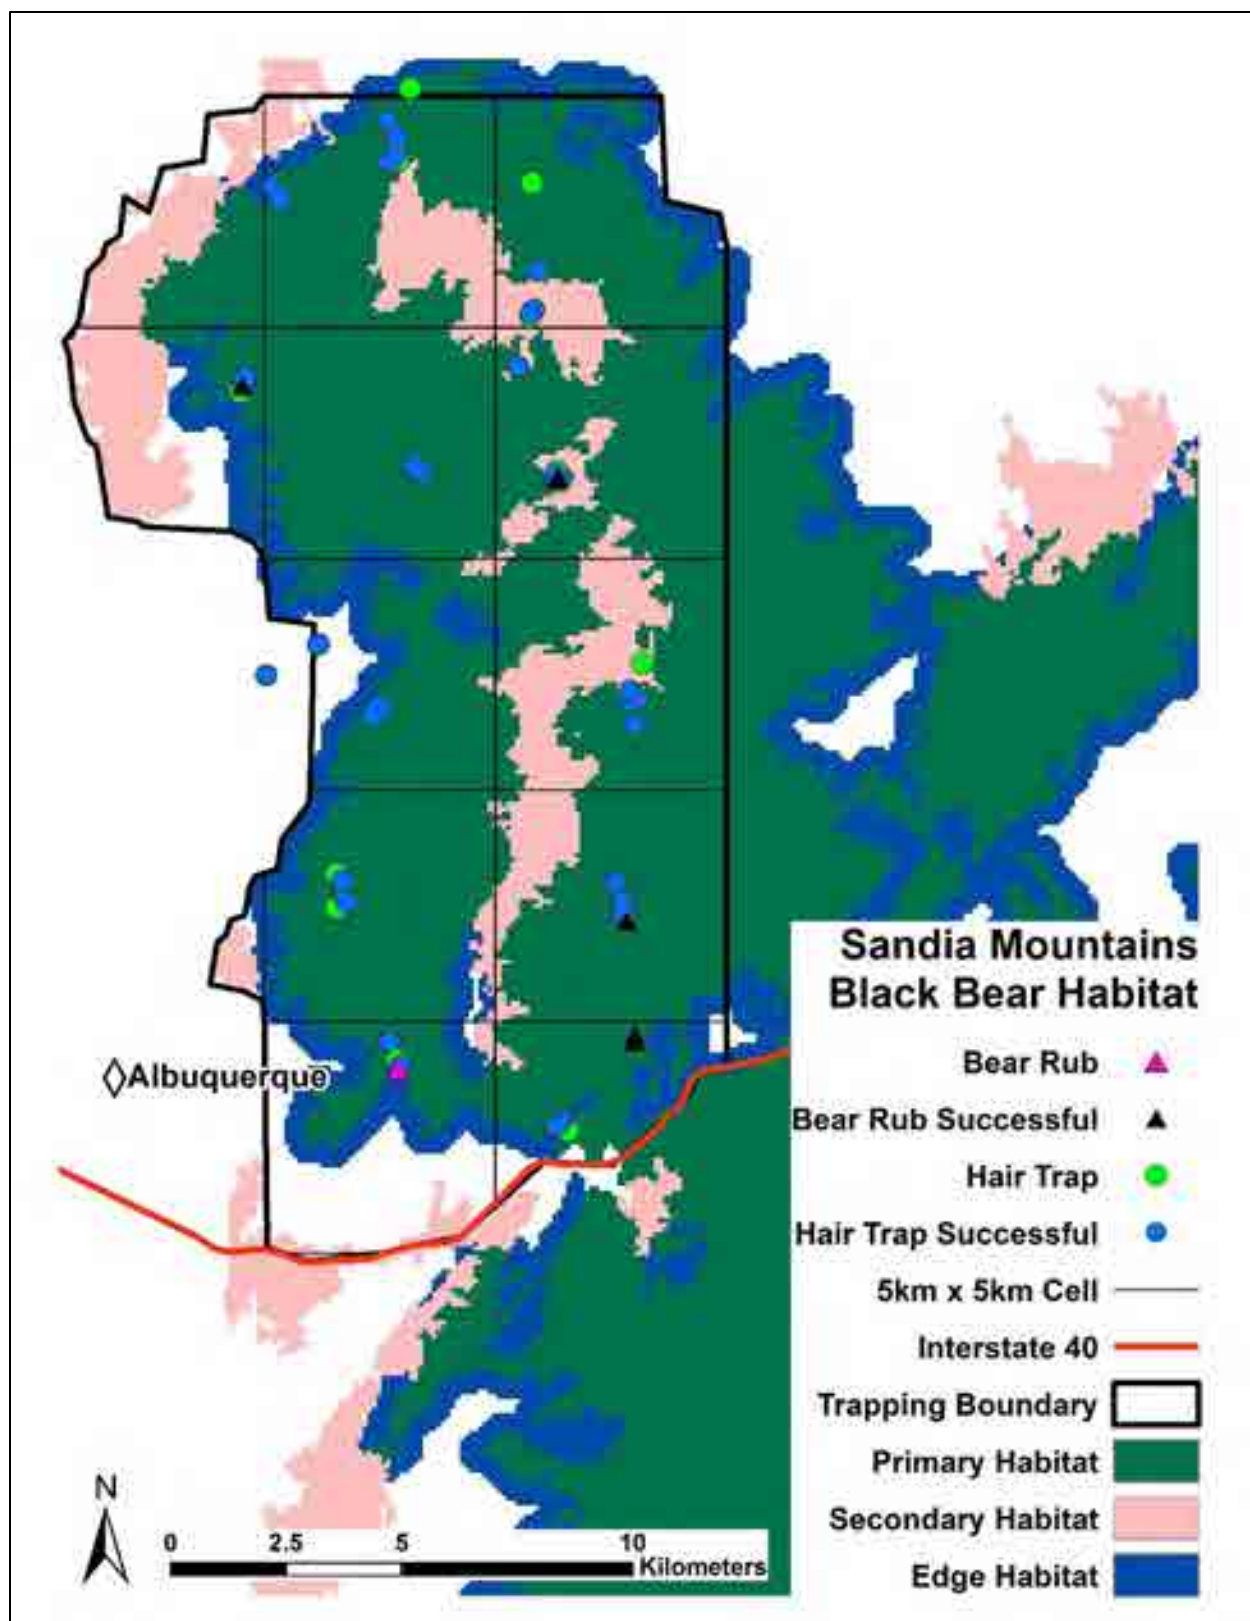

Figure 3. Black bear habitat identified by Costello et al. (2001) overlaid with hair traps and bear rubs set for the Sandia Mountains, NM in 2014.

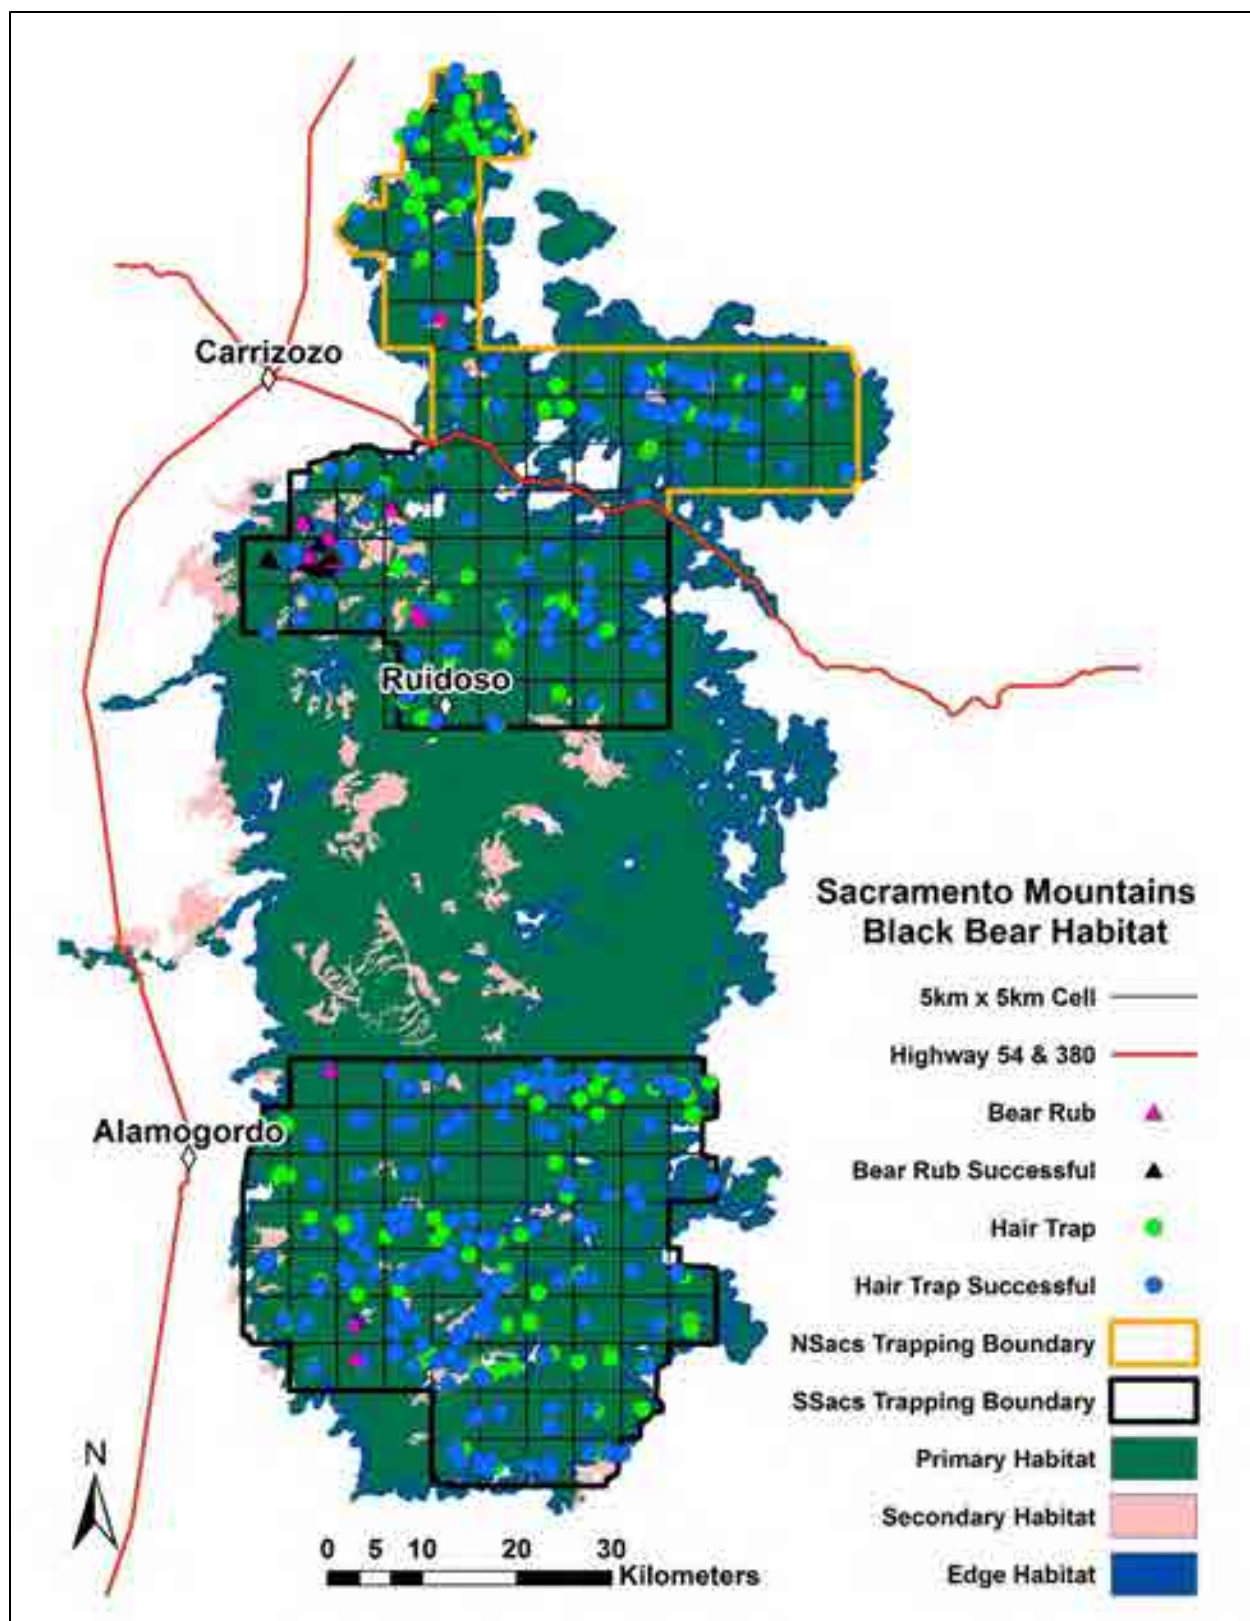

Figure 4. Black bear habitat identified by Costello et al. (2001) overlaid with hair traps and bear rubs set for the Sacramento Mountains, NM in 2014.

Figure 5. Number of unique individuals detected by hair traps and bear rubs combined for each sampling occasion in the Northern (NSC) and Southern (SSC) Sangre de Cristo, Sandia, and Northern (NSacs) and Southern (SSacs) Sacramento Mountains, NM.

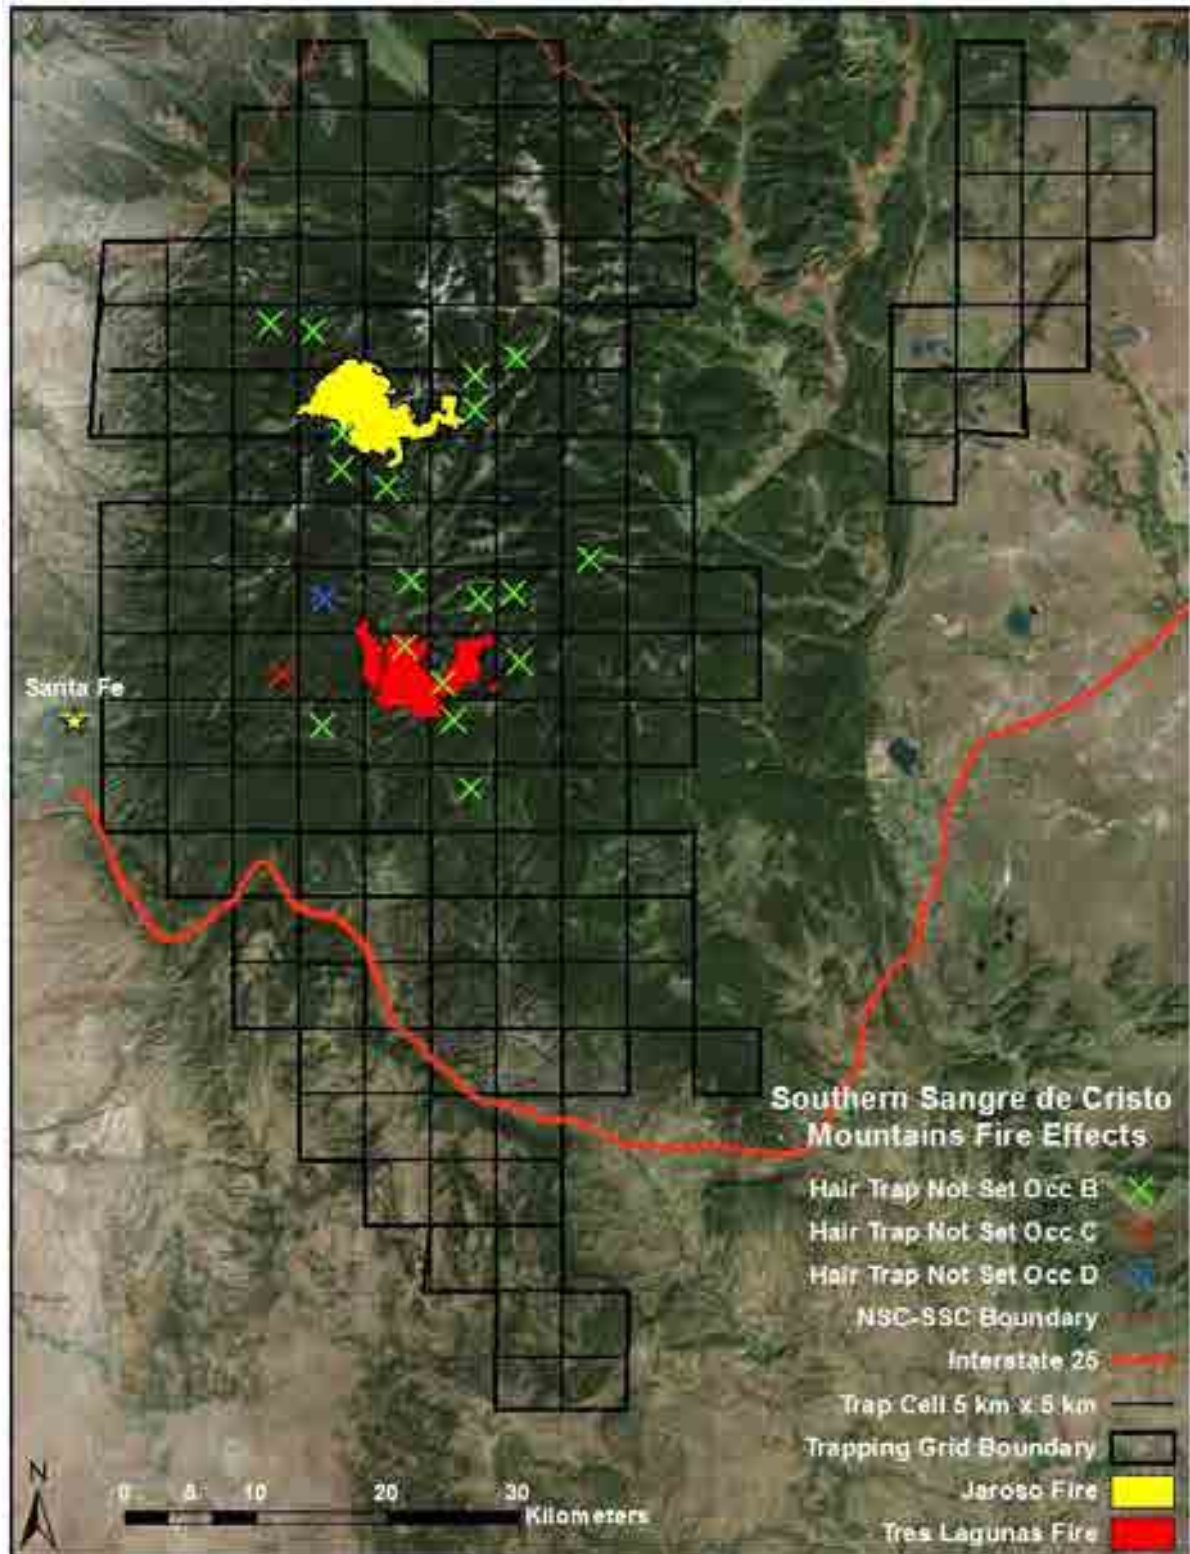

Figure 6. Map of hair traps not deployed due to the Jaroso and Tres Lagunas fires in the southern Sangre de Cristo Mountains, NM in 2013.

Figure 7. Mean montly ultraviolet index (UVI) generated by the National Oceanic and Atmospheric Administration showing estimated noontime intensity of ultraviolet radiation coupled with the World Health Organization human health hazard UVI classification for Albuquerque, NM, Atlanta, GA, Boise, ID, Buffalo, NY, Charleston, SC, Cheyenne, WY, Denver, CO, Memphis, TN, and Phoenix, AZ, USA in 2012.

Table 1. Field sampling summary statistics allocated by number of detector types set (hair traps = HR & bear rub = BR), for the Northern (NSC) and Southern (SSC) Sangre de Cristo, Sandia, and Northern (NSacs) and Southern (SSacs) Sacramento Mountains, NM.

Study Area	HT ^a	HT Sites ^b	HT Hit ^c	HT Effort ^d	BR ^a	BR Effort ^d
NSC	256	1018	0.36	28,183	46	3,730
SSC	141	537	0.29	15,768	25	1,816
Sandias	12	69	0.42	979	7	293
NSacs	37	217	0.41	2,990	1	56
SSacs	111	656	0.29	9,090	33	1,112
Total	557	2497	0.33	57,010	112	7,007

^a Number of sampling detectors set.

^b Number of sampling detectors cumulatively summed across all sampling occasions.

^c Number of traps which collected ≥ 1 hair sample over the all sampling occasions.

^d Sampling effort represented by the number of days a sampling detector (hair trap & bear rub) was set summed across all detectors and all sampling occasions.

Table 2. The total number of hair samples collected across sampling occasions (1-6) and detector type (hair trap:bear rub) , and the overall total for the Northern (NSC) and Southern

Study Area	1	2	3	4	5	6	Total
NSC	312 (299:13)	634 (582:52)	597 (571:26)	374 (339:35)	-	-	1917 (1791:126)
SSC	145 (141:4)	125 (124:1)	184 (183:1)	273 (246:27)	-	-	727 (694:33)
Sandias	8 (8:0)	30 (30:0)	23 (19:4)	28 (19:9)	51 (35:16)	37 (31:6)	177 (142:35)
NSacs	49 (49:0)	58 (58:0)	77 (73:4)	75 (73:2)	123 (118:5)	82 (79:3)	464 (450:14)
SSacs	93 (93:0)	143 (143:0)	183 (179:4)	135 (118:17)	129 (118:11)	115 (97:18)	798 (748:50)
Total	607 (590:17)	990 (937:53)	1064 (1025:39)	885 (795:90)	303 (271:32)	234 (207:27)	4083 (3825:258)

(SSC) Sangre de Cristo, Sandia, and Northern (NSacs) and Southern (SSacs) Sacramento Mountains, NM.

Table 3. Number of alleles, expected heterozygosity (H_E), and observed heterozygosity (H_O) for eight microsatellite markers used for individual identification of American black bears in the Sangre de Cristo Mountains, Sandia Mountains, and Sacramento Mountains, NM.

Marker	<u>No. Alleles</u>			<u>H_E</u>			<u>H_O</u>

Abstract: We surveyed 52 jurisdictions across continental North America to gather comparative information on management strategies for American black bear (*Ursus americanus*) for the late 1980s and the start of the 21st century. Specifically, we asked about: population estimates and targets, harvest objectives and hunting methods (spring hunt, use of bait, use of dogs), hunter and harvest data, and trends in human–bear conflicts. Most population estimates were derived through a subjective process of extrapolation and expert opinion and were used as the basis for adjusting management practices. In 17 jurisdictions that had spring hunts, estimated black bear populations increased by 6%, compared to a 51% increase in the 21 jurisdictions with fall-only seasons. Estimated populations increased by 87% in the 14 jurisdictions without hunting seasons. Another 10 jurisdictions had reports of occasional transient bears but no resident population. Jurisdictions with liberal hunting regimes tended to maintain human–bear conflict at stable levels, whereas those with more restrictive regimes appeared to experience a growing trend. We suggest that the goal of management should be to balance the goals of maintaining viable black bear populations, safeguarding human welfare and property, and satisfying the needs of stakeholders in a cost-effective manner. Hunting and proactive education and awareness programs are keys to achieving that balance. By setting appropriate harvest objectives and hunting methods to regulate the density and distribution of black bears, in conjunction with measures to deter bears from associating people and dwellings with food, agencies should be better able to manage for human–bear conflict in the 21st century.

Key words: American black bear, animal care, animal rights, baiting, dogs, human–bear conflict, lethal and non-lethal control, management, pets, population estimate, spring hunt, trap-and-transport, *Ursus americanus*

Ursus 18(1):72–88 (2007)

Prior to and during most of the 20th century, black bear (*Ursus americanus*) habitat across North America diminished and became fragmented (Hellgren and Maehr 1992) as agriculture and logging expanded, linear development (railways, powerline corridors, access roads) extended, and human settlements grew. Early settlers killed black bears indiscriminately for food and market value, as well as in defense of people, livestock, and crops (Alexander 1890, Cardoza 1976). However, during the 20th century, the value of wildlife and the need for active conservation became recognized through laws and policy (Reiger 1986, Miller 1990).

Estimated black bear populations in the United States grew by 13% from 1970 (Cowan 1972) to the late-1980s (Garshelis and Hristienko 2006) and were

considered stable by Miller (1990). Many factors likely contributed to the recovery and increase, including removal of bounties, reduced killing as ‘vermin,’ implementation of conservative hunting seasons and regulations (particularly the protection of females and cubs), hunting and firearm restrictions around communities, reduced hunter access to private land, and designation as threatened or endangered where applicable. In conjunction with reduced mortality, suitable habitat expanded through the natural succession of abandoned and converted farmland, logged and burned areas, and through increased availability of human-sourced foods such as garbage, birdfeed, and crops. Now that black bear populations have been restored over most of their range, the focus of management is shifting from increasing populations and providing recreational hunting opportunities to resolving issues

³hank.hristienko@gov.mb.ca ⁴john_e_mcdonald@fws.gov

brought about by abundance (Organ and Ellingwood 2000).

Concurrent with the expansion in numbers and distribution of bears and people, human–bear conflicts have increased, as evidenced by governments drafting policies and legislation to deal with problem bears, more scientific studies on the subject, and increased coverage in the popular media. Many of these issues (crop damage, vehicle collisions, and residential property damage) are similar to other human–wildlife conflicts; however, unlike most other wildlife species that conflict with people (with the exception of large cats, *Felis* spp.), black bears can be a threat to personal safety. These concerns have been fueled by media reports of bear–human encounters involving human injury, including 12 fatalities since 2000. These deaths account for 21% of all recorded black bear-related fatalities since 1900 (S. Herrero, University of Calgary, Calgary, Alberta, Canada, personal communication, 2006).

The objectives of this paper are: (1) to report on the status of black bear populations and their management in North America at the start of the 21st century, and (2) to offer our perspective on managing black bear populations as we move forward.

Status determination

Ten provincial, 2 territorial (Nunavut, Canada, was combined with the Northwest Territories for comparative purposes), and 49 state wildlife agencies in continental North America were contacted by telephone in 2002 to initiate contact and to identify which jurisdictions allowed hunting of black bears. Later that year, a survey was sent via email to identify hunting methods and trends in black bear populations and human–bear conflicts. In 2004, these jurisdictions were resurveyed to gain information on bear management planning, legal hunter harvests, and regulations concerning the feeding of bears.

The first survey was based on McLaughlin and Smith (1990), who summarized management strategies practiced by 41 jurisdictions in the late 1980s. Managers were asked to estimate population size and assess trend (stable, growing, declining) and severity of (manageable, serious, minimal) human–bear conflict during 1987–1989 and 1999–2001. Managers were asked to declare whether population estimates were based on empirical data (densities

derived from field research conducted within the jurisdiction) or educated guesses. Respondents were also asked to identify which harvest management practices (spring hunting, fall hunting, baiting, use of dogs) were in place during these periods and to summarize the number of nuisance complaints, bears relocated, bears destroyed, total compensation paid for damage caused by bears, and program delivery costs.

Subsequent contacts were made to resolve questions and to ensure that questionnaires were completed. In June of 2003, all respondents were asked to verify the accuracy of the tabulated responses from the 2002 survey.

A second survey was emailed to the same contacts in February 2004 asking whether their agency had a formal black bear management plan during 1985–2001, or by 2004, and if they had a black bear population management target, harvest objective, or both. In the absence of a management plan, the agency was asked if they followed an unwritten policy (as expressed by members of a regulatory board or in press releases by agency management). Agencies were also asked to identify any regulations prohibiting the feeding of bears, intentional or inadvertent, and the year they were enacted.

Each manager was asked to provide the following harvest data for each year from 1985 to 2001 inclusive; total males harvested, total females harvested, total harvest, and number of bear hunters. The average number of black bear hunters, black bears harvested, and the percent of female bears taken during 1987–89 and 1999–2001 inclusive was computed for each jurisdiction. In instances where data were not available for the periods requested, the closest 3 years of complete hunter harvest information (e.g., Michigan, 1990, 1991, 1992) was averaged. If a jurisdiction suspended a hunting practice, we summed hunter harvest data with equal intervals pre-and-post change (e.g., Colorado suspended baiting, spring hunting, and hound hunting in 1994 thus, we calculated pre-change as 1986–93 and post-change as 1994–2001).

Results

Responses to both email surveys were received from all 10 provinces, 2 territories and 49 states in continental North America. Twenty-two agencies (1 provincial and 21 state) reported no bear hunting season or no resident black bear populations.

Table 1. Hunting seasons, legal methods, estimated population sizes (as reported by provincial bear biologists), and current nuisance levels for black bears in Canadian provinces for the late 1980s and 2001.

Trends in black bear populations

Four of 11 Canadian jurisdictions reported increases in estimated bear populations (Table 1) between 1988 and 2001, although in 2 of those cases the estimated ranges overlapped. The remaining 7 jurisdictions reported stable population estimates. All of the Canadian jurisdictions except Prince Edward Island (where black bears have been extirpated) allowed some form of bear hunting.

Of 33 US states that reported resident black bear populations in both 1988 and 2001, 28 reported an increase in estimated abundance during that period (Tables 2, 3). Some states reported wide population ranges and others reported a single number without any estimate of variation. Three states reported a stable population over the interval and 2 states (Alabama, Montana) reported decreases. Fifteen states reported increases $\geq 100\%$ during the interval (Tables 2, 3). Nine states explicitly stated they used empirical data (Florida, Kentucky, Massachusetts, Minnesota, New Jersey, North Carolina, Pennsylvania, Utah, and Wisconsin) to derive their estimates. Methodologies used in the remaining jurisdictions ranged from fairly rigorous mark–recapture or modeling exercises using field data to educated guesses.

Trends in black bear management planning

Five of the 11 Canadian provinces and territories that hunted bears reported having a formal management plan by 2001 and 1 had a draft plan by

2004. Of the 6 provinces with management plans, 3 set population targets and harvest objectives and 1 set a harvest objective but no population target. The 2 remaining provincial management plans did not specify a population target or harvest objective.

Eighteen of 28 states that hunted bears reported having formal black bear management plans by 2001 and 21 states reported having a plan by 2004. Of these 21 states, 3 reported having a specific population target and harvest objective, 4 states had a population target but no harvest objective, and 1 state had a harvest objective but no population target. The 13 remaining state management plans did not identify a population target or harvest objective.

Harvest and hunters

Of 10 Canadian jurisdictions that had estimates of hunter numbers for both intervals (early: 1987–89, late: 1999–2001), only Nova Scotia reported increases from the early to late interval (Table 4). The decreases in the other 9 jurisdictions ranged from 2% to 210% (Table 4).

Eighteen US states had estimates of hunter numbers for both intervals (Table 5). Of those, 15 reported increases in estimated hunter numbers between the intervals, ranging from 14% to 238% (Table 5). In each state that prohibited baiting, spring hunting, hound hunting, or some combination of those methods (Colorado, Massachusetts, Oregon, Washington), hunter numbers increased by 32% to 112% for equal intervals, pre-and post

change. Fourteen of 41 US states that reported having resident bear populations in 2001 did not allow any bear hunting, although Florida did have a hunting season in 1988 (Tables 2, 3). Since 2001, New Jersey (2003) and Maryland (2005) opened bear seasons after 33 and 50 year closures, respectively. For some states (Arkansas, Georgia, Idaho, Maine, North Carolina, New York, Virginia, Vermont), no separate bear hunting license or permit is required to hunt bears during some seasons, thus these hunter numbers may not encompass all hunters eligible to take bears.

In the 10 Canadian jurisdictions that had harvest estimates for 1987–89 and 1999–2001, 6 provinces reported increases, despite hunter numbers decreasing in 5 jurisdictions (Table 4).

Twenty-three of 26 US states that had estimates of total bear harvest for both intervals reported increases (Table 5). Arizona and Utah reported decreases in hunter numbers and harvest between

intervals, and Wyoming reported a decrease in hunter numbers and a relatively small increase in the average harvest (Table 5). Utah intentionally reduced the number of licences to reduce harvest. Two of the 3 states that banned hound and bait hunting (Oregon, Washington) reported 8% and 6% harvest decreases for equal intervals pre-and-post change, whereas Colorado reported a 28% increase. In Massachusetts, which banned hounds in 1996, the bear harvest increased by 26% between the pre-and-post intervals (377 and 476, respectively).

Although total big game license sales decreased by 1.5% in 18 US states between 1991 and 2001 (US Fish and Wildlife Service 2004), black bear license sales and harvest increased by 62% and 65%, respectively (Table 6). The trend in hunter numbers in Canada for the same period was reversed, decreasing by 40% while the harvest increased marginally by 2%. Black bear license sales in both countries represented <6% of total big game license sales.

Black bear hunting methods

Each of the 8 Canadian jurisdictions that allowed hunting bears with bait in 1988 allowed baiting in 2001 (Table 1). Baiting was mandatory in Nova Scotia. Ten of 11 jurisdictions in Canada allowed spring hunting in 1988, and 9 of 11 held spring hunts

in 2001 (Table 1). Ontario eliminated the spring season in 1999. Three jurisdictions allowed the use of hounds in 1988 (Table 1). In 2001, British Columbia and Ontario allowed hounds, but Quebec prohibited hunting with hounds in 1998.

Twelve of 28 states that hunted bears in 1988 allowed baiting (Table 2). In 2001, 10 of 27 states allowed baiting, with Colorado (1994), Oregon (1994), and Washington (1996) banning baiting and Arkansas permitting it in 2001. Eight states allowed at least limited spring bear hunting in 1988 (Table 2). In 2001, 7 of those states allowed some spring hunting whereas Colorado prohibited spring hunts in 1994. In 1988, 22 of 28 states allowed the use of hounds to hunt bears (Table 2). In 2001, 17 of 27 states allowed hunting with hounds, with Colorado (1994), Massachusetts (1996), Oregon (1994), and Washington (1996) enacting prohibitions on the use of hounds. Florida allowed hounds in 1988, but banned all bear hunting after 1993.

Human–bear conflict management

Ten jurisdictions provided partial or full compensation for damages to beehives, crops, or livestock caused by black bears. New Hampshire, West Virginia, Wisconsin, and Manitoba compensated for all these damages, whereas Pennsylvania and Ontario covered poultry, livestock, and beehives. Utah covered only livestock, Alberta and Colorado covered crops and livestock, Wyoming covered beehives and livestock, and Saskatchewan covered grain crops and beehives. California, Michigan, Minnesota, North

tentional or inadvertent feeding of wildlife in a manner that could contribute to the habituation and food-conditioning of a bear. By 2004, 2 additional Canadian provinces (Alberta, Manitoba) and 4 more US jurisdictions (Florida, Kentucky, New Jersey, Pennsylvania) introduced anti-feeding regulations. In 2001, 10 jurisdictions (British Columbia, California, New Jersey, Michigan, Minnesota, New Hampshire, North Carolina, Oregon, Washington, Wisconsin) had formalized systems to document human–bear conflict which included a database to enter and retrieve data.

Perspective on black bear management Trends in populations

Management agencies have taken conservative approaches to managing black bears during what can be termed the population restoration phase of the latter half of the 20th century. This was due, in large part, to early research that portrayed the species as having one of the lowest rates of reproduction of any land mammal in North America (Jonkel and Cowan 1971), being among the slowest reproducing terrestrial mammals in the world (Bunnell and Tait 1981), and vulnerable to over-harvest (Bunnell and Tait 1980). More recently, research has indicated that some bear populations in the east and midwest are more productive than earlier reported, with most females having their first litters at 3 years old (some at 2 years) and a mean litter size for adult females approaching 3 cubs (Alt 1989, McLaughlin 1998, McDonald and Fuller 2001). Recruitment rates of around 1 cub per year, assuming 25–30% mortality (Bunnell and Tait 1985), are comparable to many hunted ungulate populations. Although most ungulates become reproductively mature at 1–2 years of age, their reproductive potential rarely extends past 15 years (V. Geist, University of Calgary, Calgary, Alberta, Canada, personal communication, 2006); black bears can successfully reproduce into their mid-twenties (Alt 1989, McLaughlin 1998, H. Hristienko unpublished data). For Manitoba, that means that >11,600 cubs are born each year if the black bear population has 25,000 animals, a female:male sex ratio of 55:45 (Pastuck 2001), 33% of females are available to breed in any year (Alt 1982), and an average litter size of 2.56 (Hristienko et al. 2004). Using an annual mortality rate of 18–47% for cubs (Kolenosky 1990)

results in an estimated 6,160–9,530 yearlings searching for a home range each year.

Pooled population estimates for North American black bear populations suggest a growth rate of 2% per year (Garshelis and Hristienko 2006) since the late 1980s. Decker et al. (1981) suggested that high bear populations will inevitably lead to human–bear conflicts because of the bear's attraction to human food sources, implying an association between the population densities of humans and bears. Because we are unlikely to be able to control the density and distribution of people, we are left with controlling the density and distribution of bears to reduce conflict between the two. That leads us to question: How do agencies manage black bear populations to sustain their abundance and distribution while maintaining them at levels that safeguard human welfare and property (wildlife acceptance capacity) in a cost-effective manner? By how agencies manage we mean not just philosophically in terms of how many bears there should be, but also mechanistically in terms of the practices employed to reach those goals.

Black bear management

Black bears are a long-lived species that occupy the top of the food chain and are capable of rapidly altering their behavior to adjust to environmental change (Ayers et al. 1986, Stirling and Derocher 1990). There is no evidence to show that black bear populations in settled areas of North America self-regulate or that bears dispersing beyond the periphery of their current range would fare poorly (Garshelis 1994). In fact, suburban woodland areas are becoming sanctuaries for bears, primarily because they provide food in the absence of significant perceived risks (to bears). A Nevada study attributed many traits of urban-interface bears to the availability of human foods, including the 70–90% smaller home ranges, 30% greater body mass, higher reproductive success, and later denning and slightly earlier emergence than wildland bears (Beckmann and Berger 2003a,b). Similarly, in New Hampshire and New Jersey, female bears occupying human residential areas had smaller home ranges than reported for bears in nearby less developed areas (Ellingwood 2003, MacKenzie 2003).

Animal-rights activists want no human interference through hunting, trapping, or problem animal destruction, so bears can 'naturally' seek their own population levels (R. Carmichael, Chair of Animal

Ursus 18(1):72–88 (2007)

Use Committee, International Association of Fish and Wildlife Agencies [IAFWA], Winnipeg, Manitoba, Canada, personal communication, 2004). Both provincial and state wildlife management agencies and most animal-care organizations attempt to manage animal populations but use different means to achieve the same ends. Agencies manage free-ranging populations and attempt to provide human use within habitat limits (at or below biological carrying capacity), whereas animal-care organizations manage captive individuals based on the availability of space in shelters and homes (that is, at or below carrying capacity). In either case, when carrying capacity is exceeded, animals are removed by hunters or by a veterinarian or caregiver. Even with subsidized spaying and neutering programs, many pets are euthanized each year. The CBS News program *48 Hours* reported that in the US, 5 million domestic dogs and cats were deliberately killed in 2001.

If left unchecked, black bears can be a limiting factor to other species—moose (*Alces alces*) in Alaska (Osborne et al. 1991) and woodland caribou (*Rangifer tarandus caribou*) in Newfoundland (Mahoney et al. 1990). In the case of black bears living closely with people, bears can present the same type of nuisance situations as raccoons (*Procyon lotor*), foxes (*Vulpes* spp.), or uncontrolled pets (McLaughlin and Beck 1996). We believe public tolerance for these nuisances will erode and bear populations eventually will have to be controlled. This may be by hunters, by citizens (either legally or illegally), or by government agencies at public expense.

Lethal control

Hunting programs are usually structured to suit the demographics, geography, and local traditions of jurisdictions. The hunting methods permitted largely depend on hunter numbers, access, terrain, effectiveness, humaneness, public safety, and local culture, concurrent with species population dynamics (distribution, density, behavior, reproduction, recruitment, longevity, and natural mortality), all filtered through the lens of politics.

In addition to generating revenue to support wildlife conservation programs, provincial and state wildlife agencies view hunting as “a safe, legal, responsible use of the wildlife resource and a legitimate and effective means to control over-abundant game species in a cost-effective manner” (Wolgast et al. 2005:19). Hunting has been embraced by agencies as a core element of what is termed the North

American model of wildlife conservation (Prukop and Regan 2005). A well-managed harvest system achieves a sustained yield and places a positive value on black bears in terms of economic, social and biological benefits. The alternative to a goal-driven hunting program is often a reactive, individual-based approach to dealing with nuisance bears (McDonald 2003). Hunted populations seem to be more wary of humans (McCullough 1982, Herrero 1985, Swenson 1999) than unhunted populations.

Provincial and state human demographics appear to have a greater effect on hunting seasons than biological factors. We identified an east and south versus a west and north division, and urban jurisdictions tend to have more restrictive hunting regimes than jurisdictions with largely rural populations (Fig. 1). Estimated bear number increases were greater (87%) in the 14 jurisdictions that had resident populations but did not permit hunting than in jurisdictions that did permit hunting: 51% in the 21 jurisdictions that had only a fall-season and 6% in the 17 jurisdictions that had both spring and fall seasons (Fig. 2). We recognize that the estimates provided by managers were not always based on precise methodology and thus do not reflect absolute population trends (Garshelis and Hristienko 2006), and that some of the increases may have been by design. However, these estimates serve a management purpose and are necessary for adjusting bear harvests according to a perceived population trend.

Pennsylvania, Virginia, and Wisconsin all reported increasing bear populations and subsequent conflicts even though harvest rates in recent years were >20%. Previously, losses to hunting of 8% (Kolenosky and Strathearn 1987) and 14.2% (Miller 1990) were thought to be excessive for Ontario and North America, respectively.

Western and northern populations, where food is less abundant and hard mast often absent, certainly may need to be managed more conservatively than eastern populations. However, to reduce the high levels of human–bear conflict in many jurisdictions, harvest objectives to reduce or stabilize bear populations will need to be increased. This will require wildlife management agencies to change their philosophy *vis a vis* black bears from restoration to management (McDonald 2003). Even if these higher harvest objectives are significantly exceeded in a year, few bear populations should be at any serious risk. Through harvest monitoring and knowledge of population dynamics, agencies should be able to

Fig. 1. (a) Hunting season strategies across North America and the associated trend in human–black bear conflicts, 2001. (b) Range of black bear population estimates and growth in North America within associated management strategies, 2001.

respond quickly by reducing harvest objectives as has been demonstrated in some states (New Hampshire; M. Ellingwood, New Hampshire Department of Fish and Game, Concord, New Hampshire, USA, personal communication, 2006).

Opponents of bear hunting argue that hunting is not effective at reducing human–bear conflicts because of the low probability that hunters will kill the bears that actually cause problems, and that hunters preferentially target large males. By removing 1–5-year-old bears, the age group responsible for >70% of all reported nuisance conflict (Garshelis 1989, Shull 1994, Landriault 1998, Brown and Hamr 1999) and which are represented in the same proportion in most populations and harvests (Shull 1994, H. Hristienko unpublished data), managers are being proactive in addressing the

density and distribution aspect of the human–bear conflict issue.

Because variability in bear complaints is related to so many factors, it is difficult to arrive at a specific cause-and-effect relationship to explain large swings in nuisance activity from one year to the next. That said, New Jersey reduced bear complaints by 42% in 2004, the year after its first bear hunt in 33 years (Wolgast et al. 2005). With fewer bears, it is natural to assume that there would be fewer human–bear interactions resulting in fewer complaints. Although some nuisance bears are killed during a regulated hunting season, thereby eliminating further problems, many nuisance bears are relatively invulnerable to hunters because of access and firearm restrictions in and around communities. We believe hunter access will soon be (if it is not already) one of the

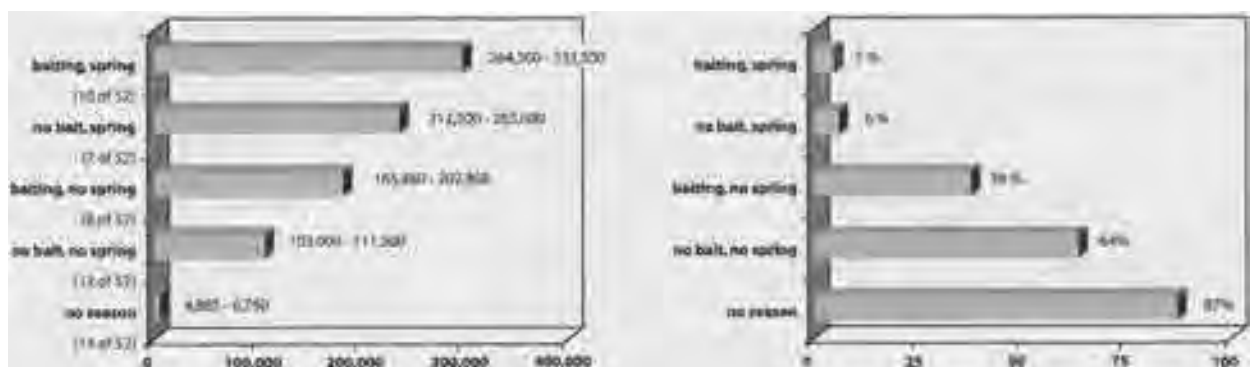

Fig. 2. Range of black bear population estimates and growth in North America within associated management strategies, 2001.

Ursus 18(1):72–88 (2007)

largest obstacles to resolving the most controversial bear population management situations, as it is for white-tailed deer (*Odocoileus virginianus*) management.

Opponents of bear hunting further condemn the practice on ethical grounds and claim it is unnecessary to manage populations. Animal-rights activists, frustrated in most broad attempts to curtail hunting through legislative, judicial, and agency regulatory routes, have adopted a strategy—often using the ballot initiative where available—of challenging elements of hunting that research has identified as most offensive to or least understood by non-hunters, that is, claiming that hunters only seek a trophy, that it is unsafe, that baiting is unsporting, that the use of dogs is cruel, that spring hunting is unfair, or that shooting mothers orphans their cubs. (Pacelle 1998).

Bear hunting methods

Baiting. It is important to distinguish between using attractants to lure bears in hunting situations and the deliberate or inadvertent luring of bears in nuisance situations. Baiting for the purpose of hunting typically occurs in forested habitat, removed from direct interaction with humans, and bears in these situations tend to be secretive and wary whereas bears that interact with humans in suburban settings can become habituated and food-conditioned as they learn to associate humans and food without negative consequences. Habituated bears may become increasingly brazen to the point of being aggressive when they learn humans can be intimidated, as has been demonstrated with coyotes (*Canis latrans*) and mountain lions (*Felis concolor*) (Timm et al. 2004). Swenson (1999) concluded that if bears are to maintain their wariness of humans, human-derived foods must not be available to them.

Opponents of baiting argue that it epitomizes unfair chase, it causes littering problems, promotes the transmission of disease, conditions bears to become nuisances, and increases bear vulnerability to hunters. Proponents of baiting argue that it enhances the safety of hunters and non-hunters (particularly where elevated stands are used), is appropriate for settings where visibility is limited and spot and stalk hunting is impractical, helps maintain consistency in the number of bears harvested annually, distributes hunting pressure rather than leaving large tracts of difficult (from a hunting perspective) habitats unharvested and

optimal habitat overhunted, can target the male segment of the population, can increase selectivity against females accompanied by cubs, improves the opportunity for a humane kill, can increase harvests where chronic depredation or other human–bear conflict is common, and provides opportunities for hunters to experience and photograph all types of wildlife. All these points must be considered by agencies when developing an effective harvest strategy to meet management objectives.

Animal-rights activists argue that baiting bears is antithetical to hunting, while others oppose baiting on the grounds that they believe the practice preconditions bears to foods associated with humans. Paquet (1991:2) conceded that for the Riding Mountain area of Manitoba there was “no evidence that bears exposed to baits become problems in campgrounds, agricultural areas, or residential developments.” McLaughlin, in a 1996 *Outdoor Life* article, demonstrated that in Maine, where baiting typically accounts for about 75% of the harvest (Vashon and Cross 2005), bears were not conditioned to become nuisances. D. Garshelis (Minnesota Department of Natural Resources, Grand Rapids, Minnesota, USA, personal communication, 2003) has not seen evidence from capture studies in Minnesota to implicate baited bears in nuisance activities; to the contrary, nuisance bears are not the ones that have been captured repeatedly. Both Garshelis and H. Reynolds (Alaska Department of Fish and Game, Anchorage, Alaska, USA, personal communication, 2003) theorized that if baiting and nuisance behavior are linked—that is, baiting spurs bears to become nuisances, but baiting also attracts nuisance-prone bears—then, in a heavily hunted population, baiting may remove more nuisance animals than it creates.

G. Vautour (Ontario outfitter, Massey, Ontario, Canada, personal communication, 2003) speculated that prior to the cancellation of the spring bait hunt in Ontario, 2,000 registered tourist outfitters each put out a minimum of 4,500 kg (10,000 pounds) of bait in addition to what was placed by resident hunters. The removal of >9 million kg (20 million pounds) of food, at a time of the year when it is difficult for bears to find energy-rich foods, forced bears to seek food elsewhere. He speculated that baiting stations in the spring served as intercept feeding sites (where food is placed to lure animals away from other areas) delaying dispersal until natural foods are available. In central Ontario, all

incidents of nuisance behavior by bears that were trapped and collared at bait sites began after hunters suspended baiting activities in spring, supporting the theory that baited bears depended on bait as a spring food (Landriault 1998).

During 1995–98, prior to the 1999 cessation of the spring bait hunt in Ontario, a few resource offices received a total of 2,600 nuisance bear complaints. During 1999–2002, post cancellation, these same offices received 12,426 calls (T. Quinney, Ontario Federation of Anglers and Hunters, Peterborough, Ontario, Canada, personal communication, 2005). For Manitoba, the figures for the same periods were 5,850 (average = 1,463; range = 739–2,295) and 5,838 (average = 1,459, range = 1,102–1,809). For the same periods, the numbers of bears harvested were 26,886 and 18,920 in Ontario, and 6,424 and 6,899 in Manitoba. Responding to mounting pressure to protect its citizens from nuisance bears, Ontario invested \$10 million (Canadian) during the 2 years after introducing a comprehensive nuisance bear management strategy in 2004 to reverse the trend of increasing human–bear conflicts.

We believe that baiting can be used to achieve harvest objectives in and around developed areas, perhaps even using feed mixtures specifically formulated for bears to reduce the association of people and anthropogenic foods. In our opinion, hunting from elevated stands over bait may be the most effective and safest way to hunt bears in developed areas because baiting can be used to attract bears to areas outside restriction zones or onto the land of willing landowners. Hunters are forced to take short distance shots at stationary targets with all shots from the elevated stands being directed into the ground, and bait sites can be marked to alert non-hunters to their presence (McDonald 2003).

Spring hunting. A key question regarding the ability of hunting to manage human–bear conflict is how will the season of hunt (spring versus fall) affect the number of human–bear conflicts if a given number of bears are to be killed by hunters to limit population growth? By reducing the density of bears in the spring, agencies are being proactive in addressing the density and distribution of bears before the peak problem bear season, which in Manitoba is mid-July–early September (H. Hristienko unpublished data). In years when there is an abundance of natural foods in the fall, hunting success can be reduced (Noyce and Garshelis 1997). In Minnesota, which allows baiting, hunting success

ranged from 26% (in 1994) to 43% (in 1995) from 1984 to 1995. In 2002, a year in which the fall food index was deemed high, hunting success was 14% (Garshelis 2005). Additionally, whatever population reduction gains are achieved in a fall-only season will be offset by the assimilation of dispersing yearlings the following summer.

Opponents of spring hunts contend that hundreds of cubs are orphaned (Kerr 1999) and starve when their mothers are killed (Animal Alliance of Canada 1999). All jurisdictions that have spring hunting seasons prohibit the killing of cubs or females accompanied by cubs of the year during those hunts. Manitoba demonstrated that <8% of harvested females (representing 2% of the total annual harvest) showed evidence of placental scars from the year of harvest (indicating that the female had given birth to cubs that year). Although some orphaning does occur, the number is negligible (<2%) compared to cub mortality from natural causes (Hristienko et al. 2004). In Ontario, 40% of cubs orphaned after 24 May survived until hibernation (G. Kolenosky and S. Strathearn, 1987, Survival and movements of orphan and non-orphan black bear cubs in east-central Ontario, Ontario Ministry of Natural Resources, Maple, Ontario, Canada) as did 40% of cubs orphaned after 18 June in Virginia (M. Vaughan, Virginia Polytechnic Institute and State University, Blacksburg, Virginia, USA, unpublished data, 2002).

Spring seasons can have less effect on bear population dynamics than seasons in the fall primarily because the spring harvest is largely composed of males (Jolicoeur 1997; Hristienko et al. 2004; H. Reynolds, personal communication, 2003). For this reason, Utah reinstated a statewide spring bear season in 2006 after a 14-year closure (C. McLaughlin, Utah Division of Wildlife Resources, Salt Lake City, Utah, USA, personal communication, 2006).

In addition to reducing the density and distribution of black bears before the peak of the problem bear season, hunters in a regulated spring bait hunt can take advantage of sparse vegetation that increases the detectability of cubs and can select against nursing females because they tend to be less mobile and avoid areas of disturbance. Further, spring hunts support a rural economy and the tourism industry at a time of the year when few other opportunities are available and offers hunters the opportunity to take bears when their coats are prime and when the animals are leaner and their meat more palatable than in the fall (Hristienko et al. 2004).

Ursus 18(1):72–88 (2007)

Use of dogs. Early settlers used dogs to find and bring bears to bay, and hunting with dogs made bears more timid (Alexander 1890). Today, several arguments have been put forward to oppose the continued use of trained dogs to hunt black bears. First, it is claimed that the use of dogs provides an unfair advantage for hunters and causes psychological and physical trauma to bears not ultimately killed. Techniques such as the use of radiocollars on dogs and relaying of dogs (i.e., rotating fresh dogs on to the track of a bear already being pursued by dogs) are cited as support for the unsporting claim. Second, dogs in pursuit of a bear do not respect property lines, thus trespass becomes an issue. Third, pursuing hounds may harass non-target wildlife species and sometimes catch and injure bears on the ground, particularly cubs. And finally, the dogs themselves are subject to injury from the chased bear.

Although dogs provide an advantage to the hunters, as evidenced by comparing success rates of hunters using dogs and still hunters, using dogs does not guarantee that a bear will be located, tracked, and ultimately killed. Many variables figure into the ultimate success of a hunt behind dogs, including the age of the track, weather conditions, terrain, and the condition of the dogs. Individual bears behave differently when pursued by dogs. Some are clearly agitated even when treed, but others are able to maintain comfortable distances between themselves and the dogs, periodically stopping to determine if the dogs are closing on them. Some treed bears apparently feel secure, even relaxed, and may even sleep, while dogs are baying at the bottom of the tree (Auger and Black 1995:149). Thus, it is difficult to determine just how much psychological trauma bears endure from being pursued by dogs. Pursuit during hot weather can certainly lead to physical stress on bears and dogs alike; however, most hunting seasons occur when hot weather is atypical. Bear-dog encounters on the ground can result in physical harm, usually to the dogs.

Using radiocollars on dogs allows hunters to locate lost dogs when a chase has ended and to stay in contact with the dogs when they are out of hearing range. This contact can allow hunters to determine if dogs are getting close to roads or other human activity (or vast roadless areas where contact with the dogs may be difficult to maintain) and intercept them if necessary (Elowe 1990). Use of radiocollars also helps avoid trespass or at least to resolve the

issue more directly by allowing the hunter to know where the dogs are and demonstrate to a landowner or enforcement official the ability to retrieve them. Hunting with hounds, like baiting, allows hunters to be selective when deciding whether to kill a bear because typically there is time to assess the sex and relative size of a treed bear. Further, treed bears provide relatively stationary targets allowing for good shot placement.

Non-lethal control. Human-bear conflict can be greatly reduced through non-lethal measures such as bear-proof waste management systems; electric fencing around dumps, bee hives, crops and gardens; modifying placement or configuration of field crops; and using aversive conditioning to train first-time offenders to keep away; these all reduce bear access to food and other attractants. Unfortunately, once a bear becomes habituated to humans, the removal of attractants may not change behavior (McCullough 1982).

When a bear becomes a nuisance, which for many may simply mean its presence, the public often demands action. Reactive programs, such as trap-and-transport of problem bears, do not necessarily resolve the problem because relocated bears take with them the habits they learned, and if the food incentives remain at the original site, other bears will be enticed into the same behavior, especially offspring of habituated family groups. Removing the bear without addressing the attractant (McArthur 1981) perpetuates the cycle. Finding unoccupied areas where bears can be released without being a nuisance is difficult given that the recommended distance a bear needs to be relocated is about 60 km (straight line distance) to achieve an 80% likelihood of it not returning (Alt et al. 1977, Rogers 1986, Shull 1994, Landriault 1998). It is too early to say whether aversive conditioning trains bears to stay away from human food sources. Because methods, definitions, application, evaluation, and definition of success vary, research is now being conducted to assess the availability, effectiveness, and feasibility of non-lethal means to alleviate nuisance situations, and if effective, to develop standards.

Opponents of lethal control argue that fertility control is a viable alternative. Problems with this option for black bears include the lack of approved chemical or biological sterilants for free-ranging bears, and lengthy and costly program implementation because bears would need to be handled or remotely injected to receive treatment. Further,

treated nuisance bears would likely continue to be nuisances, and dispersing bears would probably be unaffected (US Department of Agriculture et al. 2002). The National Park Service (2006) rejected the use of contraception alone to control non-native deer (*Axis axis*, *Dama dama*) in Point Reyes National Seashore, California. Their preference is to use lethal removal with long-acting contraceptives. Even in combination, their population modeling predicted it will take 15 years to achieve target population levels and will require considerable investment. Fraker et al. (2006) concluded that for New Jersey, fertility control would be difficult, expensive, and almost certain to fail.

Human–bear conflict. Black bears have adapted to thrive in landscapes with human activity for a variety of reasons (Ternent et al. 2001). What may once have been prime bear habitat, with seasonally abundant natural foods, may now be replaced with a higher quality and more dependable year-round food supply—garbage, bird feed, fruit trees, gardens, beehives, compost, and pet food. During late summer and autumn, depending on latitude, bears enter hyperphagia, a stage when fat reserves are accumulated for hibernation through increased food intake, from 8,000 kcal/day to 15,000 to 20,000 (Nelson et al. 1983). Because a bear's feeding strategy is to obtain the most calories with the least amount of effort, it seems logical that a bear would readily adapt to finding and consuming anthropogenic foods rather than foraging extensively for lower-reward natural foods, especially when there is little risk involved in acquiring them. To achieve 20,000 kcal a day, a bear would need to consume 36 kg (80 pounds) of fruit or 3 kg (6.6 pounds) of nuts, which equates to 8½ cheese pizzas, or 25 hamburgers, or 3.5 kg (7.7 pounds) of sunflower seeds.

Will (1980) reported that at that time, most states handled <50 complaints/year, citing human carelessness, ignorance, and fear at the root of most problems. Those causes still apply today as do the following 4 concerns he identified with respect to human–bear conflict: it requires significant time and resources from understaffed wildlife units, which takes away resources for other programs and activities, it lessens the stature and value of the black bear, it degrades the credibility of wildlife agencies when, in the public's view, inappropriate actions are taken, and destroying nuisance animals is a contradiction in the conservation of wildlife.

Peine (2001) reported that in most cases it took 10 to 25 years for communities to formulate policies concerning nuisance bears, often being triggered by human tragedy. He specified the unwillingness by people to modify their behavior (i.e., not my problem) and the costs associated with such programs as reasons for the lengthy process.

In the absence of population control measures in and around communities within bear-occupied habitat, negative interactions between humans and bears are expected to rise unless human behavior is changed. To achieve the most effective and long-lasting solution in preventing conflict with bears, residents and visitors will need to accept responsibility for making their properties and communities less inviting to bears, rather than responding to a bear that has already gained access to human-sourced foods or adapted to their availability. By eliminating and securing all scent (such as bird feed) and visual (such as bird feeders) attractants, conflict can be reduced significantly in years of normal natural food, reducing risk to the public (with respect to personal safety and property) and bears and lowering costs to all levels of government for problem bear control. In years when natural foods are scarce, however, significant human–bear conflict should be anticipated. Governments can mitigate these conflicts to some extent by providing counsel and limited partnered-funding opportunities, but the impetus for long-lasting change and durable solutions must originate in the affected communities.

Models for reducing conflict with bears can be found in Canmore, Alberta, and Juneau, Alaska, as well as at several national parks in Canada and the USA. Their successes resulted from investment in animal-resistant waste management systems and enforcement of garbage and anti-feeding ordinances. Civic governments and their residents acknowledged and accepted shared responsibility for the problem and had the will to find and implement the necessary measures to reduce conflict.

Management implications

Population management through conservative hunting seasons and regulations has not kept pace with the reproductive ability of the American black bear. We believe treating the symptoms of human–bear conflict will meet with limited success in

Ursus 18(1):72–88 (2007)

reducing those conflicts if bear populations are concurrently allowed to increase.

We can no longer explain away problem bear issues as being directly related to the abundance of natural foods (Poulin et al. 2003)—the more natural food, the fewer problems. Though it is safe to say that there will be fewer human–bear conflicts in years of abundant natural food, these bumper crops do not occur frequently—nor do crop failures. Records from Manitoba indicate that during 1995–2006, there were 2 years of abundance, 2 years of poor production, and 8 average years (H. Hristienko unpublished data). If the density of bears is above an average year's carrying capacity, then one would expect the trend in problem occurrences to be above the long-term average as bears travel in search for food or to remain stable to lower if the population is at or below carrying capacity. In Arkansas, Shull (1994) found that reproduction and recruitment better explained fluctuations in levels of human–bear conflict than did variation in food production and availability. For years in which recruitment of 2-year olds is atypically large, this influx could be the result of synchronized reproduction brought on by food failure (McLaughlin et al. 1994, Poulin et al. 2003) or it could be a function of a reduction in the age of first reproduction (from 5 to 4) due to a high food index in the year of reproduction or an increase in average litter size coupled with low mortality. If the former applies, one should expect a reduced cohort following the year of food failure. If not, the latter seems more plausible.

We should also no longer assume that female black bears need to be protected because they have such low reproductive capacity. Garshelis (1994:9) stated “increased mortality of dispersing sub-adult males would not be sufficient to regulate population size (true density-dependence), unless there were also repercussions for females.” By reducing the non-reproducing segment of the female component of a population (females without cubs), recruitment potential would be moderated. In some jurisdictions, harvests comprised of 40% females ($\leq 20\%$ being adults; Poulin et al. 2003) and harvest rates $>20\%$ appear to be sustainable. Managers will need to educate the public, including hunters, about the usefulness of female harvests to control bear populations before the killing of females without cubs in the spring or with cubs in the fall is accepted. As this continues to be true in the case of white-tailed deer management, this will be an ongoing campaign.

Groups opposed to hunting or to the lethal removal of bears often advance their position through emotional appeal and unsubstantiated, sensationalized, or flawed claims (Ugalde 1991). The reporting of such claims in the press and governments' varied responses (or lack of response) to them can lend credence to these claims and do a disservice to the greater public who have consistently identified a desire to be informed with empirical information (Campbell et al. 2001). Managing authorities should investigate all claims of non-lethal population control that are backed by peer-reviewed data and refute unsubstantiated claims.

Wildlife management authorities will continue to determine population targets at a large scale, but communities need to become involved in determining the levels of bear presence and types of conflict they are willing to tolerate. A considerable challenge for government is achieving local agreement and support for a management strategy that attempts to achieve a tolerance target. This is not a simple matter, given the complex variables involved, including often diametrically opposed public opinion (e.g. on non-lethal versus lethal measures, leave them alone versus not in my backyard), costs, safety concerns, and access and firearm restrictions.

A bear population management regime based on public hunting and guided by science should enable a jurisdiction to achieve its objectives of minimizing human–bear conflict while maintaining costs at manageable levels. However, if an informed public deems the significantly higher costs associated with maintaining bear populations at high levels justifiable, is willing to cover those costs from sources other than hunting license revenues, is willing to tolerate increased numbers of encounters in co-existence with bears, and does not burden wildlife agencies with liabilities associated with injuries or damage caused by an abundance of black bears, then those agencies may be required to maintain programs that attempt to manage conflict in the absence of bear population control. In situations where hunters simply are not able to kill enough bears to meet population goals, then capturing and destroying problem bears may be justifiable if adjoining bear populations are already managed near biological carrying capacity.

Human–bear conflict, real or perceived, will occur wherever humans and bears occupy the same space, at any bear density. The management of black bears

in the 21st century will require a 2-fold approach: an integrated management regime that uses public hunting to regulate the density and distribution of bears and removes individual nuisance bears, along with an aggressive education and political program that informs the public about what can be done to deter bears from associating people and dwellings with food, implements bear-proofing measures, and enacts and enforces bear-proof garbage storage and anti-feeding regulations.

Acknowledgments

Appreciation is extended to all black bear managers who devoted time and effort to this project. Without their cooperation, such a review would not have been possible. Special thanks are also extended to all employees of wildlife managing authorities for their passion and dedication to their vocation and for their successful conservation efforts. Gratitude is expressed to D. Wotton, R. Carmichael, V. Crichton, D. Pastuck, K. Rebizant, W. Lysack, and M. Campbell for their thoughtful and constructive comments and to B. Knudsen, D. Stevenson, and D. Crawford for producing the maps used in this paper and in public presentations.

Estimates of Abundance and Harvest Rates of Female Black Bears Across a Large Spatial Extent

JACOB HUMM, *Department of Forestry, Wildlife and Fisheries, 274 Ellington Plant Sciences Building, University of Tennessee, Knoxville, TN 37996, USA*

JOSEPH D. CLARK ¹, *U.S. Geological Survey, Northern Rocky Mountain Science Center, Southern Appalachian Research Branch, 274 Ellington Plant Sciences Building, University of Tennessee, Knoxville, TN 37996, USA*

ABSTRACT American black bears (*Ursus americanus*) are an iconic wildlife species in the southern Appalachian highlands of the eastern United States and have increased in number and range since the early 1980s. Given an increasing number of human-bear conflicts in the region, many management agencies have liberalized harvest regulations to reduce bear populations to socially acceptable levels. Wildlife managers need reliable population data for assessing the effects of management actions for this high-profile species. Our goal was to use DNA extracted from hair collected at barbed-wire enclosures (i.e., hair traps) to identify individual bears and then use spatially explicit capture-recapture methods to estimate female black bear density, abundance, and harvest rate. We established 888 hair traps across 66,678 km² of the southern Appalachian highlands in Georgia, North Carolina, South Carolina, and Tennessee, USA, in 2017 and 2018, arranged in 174 clusters of 2–9 traps/cluster. We collected 9,113 hair samples from those sites over 6 weeks of sampling, of which 1,954 were successfully genotyped to 462 individual female bears. Our spatially explicit estimator included a percent forest covariate to explain inhomogeneous bear density across the region. Densities ranged up to 0.410 female bears/km² and regional abundance was 5,950 (95% CI = 4,988–7,098) female bears. Based on hunter kill data from 2016 to 2018, mean annual harvest rates for females were 12.7% in Georgia, 17.6% in North Carolina, 17.6% in South Carolina, and 22.8% in Tennessee. Our estimated harvest rates for most states approached or exceeded theoretical maximum sustainable levels, and population trend data (i.e., bait-station indices) indicated decreasing growth rates since about 2009. These data suggest that the increased harvest goals and poor hard mast production over a series of prior years reduced bear population abundance in many states. We were able to obtain reasonable population abundance and density estimates because of spatially explicit capture-recapture methods, cluster sampling, and a large spatial extent. Continued monitoring of bear populations (e.g., annual bait-station surveys and periodic population estimation using spatially explicit methods) by state jurisdictions would help to ensure that population trajectories are consistent with management goals. © 2021 The Wildlife Society.

KEY WORDS abundance, American black bear, density, harvest, southern Appalachian highlands, spatially explicit capture recapture, *Ursus americanus*.

American black bears (*Ursus americanus*) are economically important, play a vital ecological role in sustaining healthy ecosystems, and are an iconic wildlife species in the southern Appalachian highlands of the eastern United States. Although bears were historically abundant in the region, their numbers declined through the 1800s into the mid-1900s because of habitat loss and unregulated hunting. Black bears were considered rare in many parts of the southern Appalachian region until as late as the 1970s, but bear numbers and their range have increased since that time because of protection and habitat recovery. Annual hunter

harvest and human bear conflicts in the mountains of Georgia, North Carolina, South Carolina, and Tennessee, USA, have increased at a steady pace (Fig. 1). Regulated hunting is the primary tool state agencies use to manage bear populations and, given the increasing number of human-bear conflicts in the region, many management agencies have liberalized harvest regulations as a mechanism to reduce bear populations to socially acceptable levels (Hristienko and McDonald 2007, North Carolina Wildlife Resources Commission 2012, Balkcom et al. 2019). Thus, managers need reliable population data for assessing the effects of management actions for black bears.

The Tri-State Bear Study Group, an informal association of university, federal, and state wildlife professionals from Georgia, North Carolina, and Tennessee, was formed in the

late 1960s in part to develop a regional bear monitoring strategy (Carlock et al. 1983). The group has since grown to include agencies from South Carolina, Virginia, and Kentucky, USA, and is now known as the Southern Appalachian Black Bear Study Group (SABBSG; Tennessee Wildlife Resources Agency 2020a). Various monitoring methods have been employed and coordinated across jurisdictional lines by the group. These methods include bait-station surveys, hunter harvest reporting, and hard mast surveys (Carlock et al. 1983, Brongo et al. 2005, Clark et al. 2005). Bait-station surveys consist of a series of baits established and later checked for evidence of a bear detection (e.g., claw or bite marks), which is used as a measure of relative abundance for monitoring long-term trends across broad areas (Miller et al. 1994, Rice et al. 2001, Clark et al. 2005). Oak (*Quercus* spp.) mast survey data have been collected across the region by state and federal agencies as a measure of annual production of this important bear food (Whitehead 1969, Wentworth et al. 1992, Greenberg and Warburton 2007). Though these techniques provide useful information, all have shortcomings, and none provide reliable estimates of bear population abundance for calculating harvest rates. Thus, better methods for monitoring natural population fluctuations and assessing the effects of management actions across large spatial (i.e., jurisdictional) extents are needed given the stressors on the bear population and the demands by the public that bears are managed according to the best available science.

Individual bears can be identified with DNA from hair samples collected from barbed wire surrounding sampling sites baited with small food rewards or scent attractants (Woods et al. 1999, Mowat and Strobeck 2000, Boersen et al. 2003). Individual capture histories can be constructed from which detection probability and, consequently, population abundance and density can be estimated. Settlage et al. (2008) used hair sampling to estimate black bear population abundance in 2 small study areas that included parts of the southern Appalachian highlands in South Carolina and Tennessee. Based on their trap-site densities in the 2 areas, they estimated that 5,517 hair traps would be needed to estimate population size in a 32,000-km² area in

the southern Appalachian region. Because of the labor and expense involved, Settlage et al. (2008) concluded that a region-wide population estimate would not be feasible.

Spatial heterogeneity in detection probabilities can occur when animals have different access to traps depending on their location in the sampling grid. This form of individual capture heterogeneity can lead to underestimates of population abundance. Methods have since been developed that explicitly account for spatial heterogeneity in capture probabilities (Efford 2004, Borchers and Efford 2008, Royle et al. 2014). These spatially explicit capture-recapture methods incorporate when an animal is captured and where it is captured to estimate detection probability and the location of each animal's activity center. The estimator fits a detection function assuming capture probabilities decline the farther a trap is from the animal's center of activity. These data allow for estimation of the spatial distribution of the animals that were captured and the animals that were not. There is no requirement that all animals have equal or even non-zero detection probabilities, and Efford and Fewster (2013) reported that spatially explicit models were robust to gaps in detector spacing and heterogeneous animal distributions. That finding allows for efficient cluster sampling designs consisting of a series of clusters arranged systematically across a defined study area. Such cluster sampling has since been evaluated and reported to be a reliable method for estimating abundance and density across extensive areas given appropriate trap spacings (Sollmann et al. 2012, Efford and Fewster 2013, Sun et al. 2014, Clark 2019). Furthermore, spatial covariates (e.g., land cover data) can be used to help explain variation in density across large and diverse spatial extents (Royle et al. 2014, Efford 2020). Humm et al. (2017) reported that cluster sampling in Florida, USA, provided reliable estimates of black bear densities in areas ranging from 5,295 km² to 13,025 km². Howe et al. (2013) and Clark (2019) reported that population estimates over even larger spatial extents can result in improved precision and reliability compared with estimates for smaller areas.

Our objective was to estimate population abundance and density of female black bears in the southern Appalachian highlands of Georgia, North Carolina, South Carolina, and Tennessee and, based on that information, use hunter-kill data to estimate hunter harvest rates by state jurisdiction. Our focus was on estimating numbers of females because of ease of estimation and cost savings and because female bears are most critical to long-term population growth and sustainability.

STUDY AREA

Our study area was composed of privately and publicly owned land in the southern Appalachian highlands of Georgia, North Carolina, South Carolina, and Tennessee, including Great Smoky Mountains National Park (GSMNP) and Chattahoochee, Cherokee, Nantahala, Pisgah, and Sumter national forests. Terrain in the region is mountainous, ranging up to 2,037 m in elevation at Mount Mitchell in North Carolina, and rugged, characterized by a mosaic of steep

slopes and ridges. The southern Appalachian highlands are composed of the Blue Ridge, Ridge and Valley, and Piedmont physiographic regions and the geology consists of folded and thrust-faulted marine sedimentary and volcanic rock. Major forest types included montane alluvial, early successional, cove, hemlock (*Tsuga canadensis*), montane oak-hickory (*Carya* spp.), xeric ridge, and high-elevation hardwood. Oaks were the predominant tree species with hickory, ash (*Fraxinus* spp.), and yellow poplar (*Liriodendron tulipifera*) being other common species. Fraser fir (*Abies fraseri*) and red spruce (*Picea rubens*) occurred at the highest elevations (National Park Service 2018) where rainfall averaged 215 cm/year. Seasons in the region were spring (21 Mar–19 Jun), summer (20 Jun–22 Sep), autumn (23 Sep–20 Dec), and winter (21 Dec–20 Mar). The flora and fauna were diverse owing to highly variable microclimates associated with varying elevation, slope, and aspect. In GSMNP alone, >1,600 flowering and 4,000 non-flowering plant species and >70 unique plant community associations were supported (National Park Service 2018). Whereas hunting was prohibited within GSMNP, black bear hunting was allowed during fall and winter in the surrounding national forests, state wildlife management areas, and private lands in each of the 4 states included in our study region.

METHODS

Study Design

We asked bear managers in Georgia, North Carolina, South Carolina, and Tennessee to submit maps of where they were interested in estimating bear abundance and what they considered to be primary and secondary range in each respective state. The intent of this request was to design a study whereby sampling intensity would be greatest in areas where bear densities were highest but with the additional objective of providing some information on areas where bear numbers may have been lower.

To reduce costs, our focus was on estimating female bear densities. Female detection probabilities are often higher than males (Humm et al. 2017) and female demographic parameters are major determinants of population trajectory (Beston 2011). Consequently, harvest and growth models for bears are often exclusively based on female demographics (Laufenberg et al. 2016). Moreover, trap spacings are dependent on home range sizes and can be optimized for 1 sex if movement dynamics differ by sex, as they do for bears (Clark 2019). Our approach was to first perform a sex test on the hair samples, then only conduct full genotyping on the female samples.

We based our sampling protocols on Clark (2019), who conducted simulations to evaluate various cluster sampling configurations and number of sampling occasions on DNA mark-recapture data for female black bears. Although a relatively wide range of detector configurations can provide reliable estimates, Clark (2019) reported that a 3-detector \times 3-detector configuration with 2,000 m between detectors, 16,000 m between cluster centers, and 6 weeks of sampling (i.e., occasions) performed well (i.e., low relative bias and

relative standard error and high confidence interval coverage) for estimating female black bear abundances and densities characteristic of the southern Appalachians. We then applied this sampling configuration to the primary bear ranges (i.e., zones) for each state (Fig. 2). We did the same for the secondary ranges except that we increased the spacing between clusters from 16,000 m to 24,000 m, thereby reducing the overall cluster (and trap) density in the secondary zone.

Spatially explicit capture-recapture models estimate the detection probability at an animal's activity center (g_0) and a scaling parameter (σ) that relates to home range. These parameters are estimated based on captures and recaptures of individual animals at different traps. We used a base density of 0.15 bears/km² in the primary zone and 0.05 bears/km² in the secondary zone, g_0 of 0.15, and σ of 1,700 m for the simulations as outlined by Clark (2019). We then simulated female bear populations in the 2 zones based on these parameters, created a trapping grid as described above, constructed capture histories, and estimated population size. The relative bias of the estimate for density (D) was -0.007 ± 0.005 (SE) and the relative standard error was $0.062 \pm <0.001$. After initiating field work, it became evident that establishing 9 sites per cluster would not be feasible under our funding and personnel constraints. Therefore, we conducted simulations based on a reduced design with 5 instead of 9 traps per cluster. The 5-trap cluster also produced estimates with low relative bias for D (0.016 ± 0.011) and relative standard error (0.102 ± 0.001), so most clusters were composed of hair traps constructed at any 5 sites from the original 9-site configuration (Fig. 2).

Field Methods

We obtained permits from the National Park Service, United States Forest Service, and numerous state parks to construct hair traps on public lands. For private lands, we first identified landowners associated with each site and requested permission via postcard, telephone, or in person. If a landowner could not be contacted or if access was not permitted, we attempted to locate another landowner within 500 m of the original site location. If access permission could not be obtained at a given site, we chose another location from the original 9-trap cluster if available.

Each hair trap consisted of an enclosure composed of 2 strands of barbed wire located 35–40 cm and 65–70 cm above the ground and stretched around 3–5 trees. We sampled Georgia, South Carolina, and the primary zone in Tennessee during 2017 and North Carolina during 2018. Tennessee Wildlife Resources Agency personnel sampled the secondary zone in Tennessee in 2018 based on our protocols, and we included those data in our analysis. We began hair trap construction in mid-May. In mid-June, we placed bait (i.e., 2–3 doughnuts) in a biodegradable bag and hung it from a line spanning the barbed-wire enclosure. We applied candy flavoring (Mother Murphy's, Greensboro, NC, USA) to a strip of cloth tied to the line as a scent attractant. We checked and rebaited the sites weekly for 6 weeks. At time of checking,

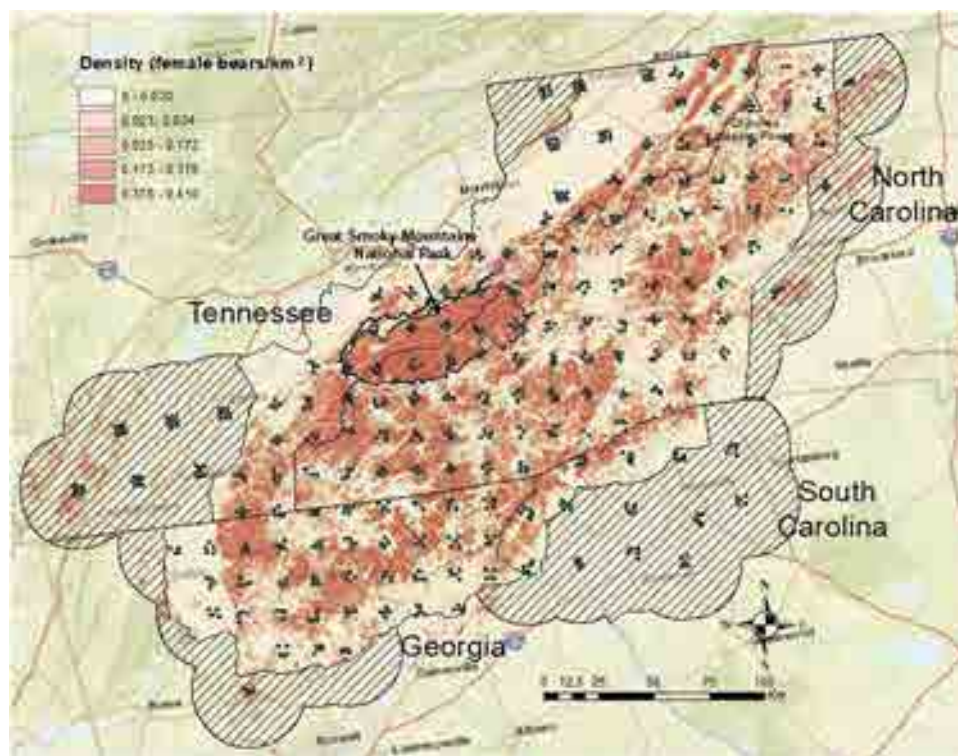

Figure 2. Density estimates for female black bears excluding cubs in the 4-state southern Appalachian region (GA, NC, SC, TN, USA), 2017–2018. Primary and secondary zones are shown for each state (secondary zones are hatched) and hair traps are depicted as green dots.

we removed hair samples with hemostats, placed them in coin envelopes, and stored them at room temperature with desiccant prior to analysis. We sterilized barbs and hemostats with a flame after each collection event to avoid contamination of future hair samples. We did not move hair traps between occasions and we removed them after the last collection event.

We obtained more hair samples than were economically feasible to genotype, so we developed a subsampling protocol to maximize the probability of detecting individual bears while reducing the probability of genotyping duplicate samples at the same site and week. Although Augustine et al. (2014) identified problems arising from subsampling in conjunction with a behavioral response to traps, subsequent analyses indicated that subsampling bias was not significant with spatially explicit estimation methods when a consistent percentage of the hair samples are subsampled from week to week (B. C. Augustine, University of Kentucky, unpublished data). Therefore, we adopted a variable subsampling strategy based on passes, whereby 1 sample selected from each site-week combination consisted of 1 pass. We made a first pass through all of the site-week combinations, choosing 1 sample at random from each site-week that met our quality control threshold of 1 guard hair or 5 underfur hairs. After this first pass of subsampling, we pre-screened those samples to identify males, which we did not analyze further. We then made a second pass through each of the site-week combinations. We took hair samples from subsequent passes from a different side of each trap if possible to try to minimize the chances of repeatedly

sampling the same individual from the same site-week. We repeated this process until we obtained the desired number of female hair samples, which was loosely based on the expected number of captures from our simulations and budget. The greater the proportion of males in the pooled sample based on the sex marker, the fewer the number of female samples that we could afford to genotype. This subsampling protocol would have allowed us to genotype additional samples if necessary.

Wildlife Genetics International (WGI; Nelson, British Columbia, Canada) genotyped hair samples. Following standard protocols (Woods et al. 1999, Paetkau 2003, Roon et al. 2005), technicians extracted and analyzed DNA based on 8 microsatellite markers (G1A, G1D, G10H, G10J, G10L, G10M, MU50, MU59) and a sex marker (ZFX/ZFY). Genotyping consisted of a first pass, cleanup, and error-check as detailed by Paetkau and Strobeck (1994) and Paetkau (2003). Technicians from WGI first purified the DNA using QIAGEN DNeasy Blood and Tissue kits under the tissue protocol. Technicians discarded samples that had low confidence scores at >3 markers on the first run of amplification. Samples that had incomplete genotypes after the first pass, but that had not been culled (i.e., those with high-confidence data for 4–7 markers), went through ≥ 1 round of reanalysis to resolve the problematic markers. The error-check consisted of an evaluation of pairs of genotypes that were similar and could have arisen through genotyping error (Paetkau 2003). Technicians re-analyzed samples with 1 or 2 pairs of mismatching markers (1MM and 2MM, respectively) and corrected the errors.

Errors produce genotypes that match at all but 1 or more rarely all but 2 markers, so the error-check protocol essentially prevented the identification of false individuals (Kendall et al. 2009).

Statistical Analysis

Once WGI genotyped the hair samples and identified females, we created individual capture histories for spatially explicit capture-recapture modeling using the R (R Core Team 2020) software package *secr* (version 4.2.2; Efford 2020). We estimated density separately for the primary versus the secondary sampling areas (i.e., we coded them as sessions in *secr*) because the trap configurations differed (16,000 m vs. 24,000 m between cluster centers, respectively). Although we sampled the North Carolina sites and some of the secondary sites in Tennessee a year later (2018) than in the other states (2017), we pooled all primary and secondary zone data across years. Although it was possible to capture female bears in different clusters, this was rare and we pooled the data if there were no captures of individual bears in >1 trap cluster in different years or zones.

For estimating what we presumed was spatially inhomogeneous density, we first defined developed land as any of the following categories based on the 30-m 2016 National Land Cover Dataset (NLCD; Yang et al. 2018): barren land, developed open space, developed low-intensity, developed medium-intensity, and developed high-intensity. Our presumption was that bear densities would be lower in developed areas. We used the R-based software package *raster* (version 3.0-12; Hijmans 2020) to reclassify those classes into a developed category. We then performed a focal mean calculation for each 30-m pixel within a square 1-km \times 1-km moving window to produce a percent developed layer. We also performed a Euclidean distance calculation on this layer in ArcMap 10.6 (Esri, Redlands, CA, USA) to create a distance to developed land layer. We divided this layer by its maximum value to rescale the layer to 0–1 to facilitate conversion of the maximum likelihood estimator in *secr*. We employed a similar procedure to create a distance to high-intensity urban development layer except that we only used the developed high intensity classification. Using a croplands data layer (U.S. Department of Agriculture 2020), we reclassified grassland-pasture and fallow-idle cropland to create an open cover layer. We then used a moving window as above to create a percent open land layer as another way to characterize human modifications to the landscape.

Black bears are associated with forest cover types so we created a percent deciduous forest layer based on a reclassification of deciduous and mixed forest NLCD classes, again with a moving window as described above. We similarly calculated the percent evergreen reclassification. We created a percent forest covariate by combining all of the deciduous, evergreen, and mixed forest cover classes. We created a percent shrub data layer from the NLCD shrubland-scrub category. We created a percent canopy cover layer from the NLCD canopy cover

dataset (Coulston et al. 2013, Multi-Resolution Land Characteristics Consortium 2020).

Bears are sometimes associated with wetlands and other riparian areas, so we used the United States Geological Survey (USGS) Hydrologic Dataset (USGS 2020a) to create percent water by performing a focal operation within a 1-km \times 1-km moving window. Black bears are commonly found in mountainous areas, so we created an elevation layer from the USGS elevation dataset (USGS 2020b). We rescaled this map layer to 0–1 by dividing each pixel by the maximum value. We also performed a focal analysis within a 1-km \times 1-km moving window to create a mean elevation layer, which was similarly rescaled. We created mean slope from the elevation data layer. Because GSMNP was considered the primary historical source of bears for our study region, we created a raster representing the Euclidean distance from a centroid in the center of the park and scaled as above. Our presumption was that bear density would decline with distance from the park; we arbitrarily chose the park center for this distance calculation. Finally, we created a raster composed of state boundaries and GSMNP to represent different management zones. Our hypothesis was that bear density might vary by jurisdiction because of different management objectives and intensities. Finally, we created a discretized mask based on a 1,000-m grid size and a 24,000-m buffer around trap sites. We assigned pixel values from each of the map layers to each grid point on the mask, and used those points as covariates for density estimation.

We used the model building strategy outlined by Zhang (2016) whereby univariate models were fit followed by multi-variable models with interactions and other effects. We first performed a correlation analysis and eliminated 1 of any pair of land use or land cover variables with correlation coefficients >0.6. We then used maximum likelihood estimators to fit a half-normal detection function in *secr*. We used the lowest Akaike's Information Criterion corrected for small sample sizes (AIC_c ; Burnham and Anderson 1998) for model selection. We considered models to be equally supported if the difference in AIC_c between the model in question and the top model was <2.0 (Burnham and Anderson 1998). We evaluated effects based on 95% confidence intervals of the of the covariate slope (i.e., β values); slopes that included 0 were indicative of no effect.

Once we identified the supported covariates on density (D), we evaluated whether g_0 or σ were affected by a behavioral response to specific trap sites (bk) and whether g_0 or σ were better described by a 2-factor finite mixture model of individual capture heterogeneity (h_2 ; Pledger 2000). Once we obtained density estimates, we estimated abundance (N) by summing the density estimates for all mask points for the various jurisdictions (i.e., if 100 mask points each have an estimated density of 0.1 bears/km² and points are 1,000 m apart, then the abundance estimate would be $100 \times 0.1 = 10$ bears). To estimate bear abundances in areas subjected to hunting, we modified the original primary zones within which we summed the density pixels to better

reflect state bear hunting regulations. We estimated standard errors and 95% confidence intervals for N using the delta method as described by Efford and Fewster (2013) with the R package emdbook (Bolker et al. 2020).

To estimate female harvest rates for the 4 state jurisdictions, we used annual female harvest data averaged across a 3-year period that included the years of our survey (2016–2018) and divided them by the adult female population size available for harvest in that jurisdiction. Bear harvests varied from year to year depending on hard mast and other factors, so we used the average to help account for that variation. All estimates were presumed exclusive of cubs based on an analysis by Laufenberg et al. (2016) with similar hair trap dimensions. The taking of cubs by hunters was prohibited in all 4 states.

RESULTS

We established 179 hair traps in Georgia, 78 in South Carolina, and 160 in the primary zone in Tennessee in 2017 and 364 in North Carolina and 107 in the secondary zone in Tennessee in 2018; these 888 hair traps were arranged in 174 clusters of 2–9 traps/cluster (Fig. 2). We did not obtain permission for all 5 sites in some clusters and up to 9 sites were established in secondary zone clusters. We collected 9,113 putative bear hair samples from those sites and submitted them to WGI for DNA analysis. Of the samples submitted, 598 samples (6.6%) did not appear to be black bear hair, 1,979 (21.7%) lacked suitable genetic material for analysis, 2,132 (23.4%) were excluded by subselection rules, 1,659 samples (18.2%) were identified as male based on a sex prescreen, 784 (8.6%) samples failed to amplify, 4 samples (<0.1%) contained DNA from >1 bear, and 3 (<0.1%) were unusable because of handling error. The remainder (1,954 hair samples or 21.4%) were successfully genotyped to 462 individual females. Genotyping success was high (88%), and observed heterozygosity (H_o) was similar across the 3 states where sample sizes were adequate (GA = 0.73, NC = 0.74, and TN = 0.73). Marker power was high, as only 2 2-mismatched

pairs were detected among the successfully genotyped bears (D. Paetkau, WGI, personal communication).

During the 6 sampling occasions in session 1 (primary zone), 665 hair traps produced 806 genotyped samples (exclusive of within-site-week duplicates) of 442 different individual female bears (Table 1). In session 2 (secondary zone), 223 hair traps produced 33 genotyped samples of 20 individual females. Only 1 individual bear was detected in >1 trap cluster, but it occurred within the same year and zone and, therefore, did not violate our assumptions for pooling.

Based on the correlation analysis, we eliminated percent developed, percent deciduous, percent canopy cover, mean slope, percent open land, elevation, and distance to high-intensity urban development from further consideration. Only 1 model was supported based on AIC_c scores (Table 2). That model included a session (primary vs. secondary zones) and an additive percent forest covariate on D and site-specific capture responses and 2 finite heterogeneity mixtures on both g_0 and σ (Table 3).

Mean female density was 0.094 bears/km² in the 66,678-km² 4-state study region and ranged up to 0.410 female bears/km², mostly centered on GSMNP (Fig. 2). Abundance (N) was 5,950 female bears in the study region (Table 4).

To estimate abundance in northern Georgia, we slightly modified our primary zone to better coincide with the primary bear range depicted in the 2019 state management plan (Balkcom et al. 2019) and calculated density estimates based on the fitted primary zone model. Mean female densities in Georgia were 0.121 bears/km² in the 9,346-km² primary zone and 0.011 bears/km² in the 4,366-km² secondary zone. The number of females in the primary and secondary zones totaled 1,181 (Table 4). Based on the 2016–2018 hunter kill data (\bar{x} = 150.0 females/year; Georgia Department of Natural Resources 2020), which included both primary and secondary zones, the mean annual harvest rate for females was 12.7% for northern Georgia, assuming abundance was constant over the 3-year period (Table 4).

^a bk = site-specific behavioral effect, h2 = 2-factor finite mixture for individual detection heterogeneity, GSMNP = Great Smoky Mountains National Park.

Mean estimated female density in North Carolina was 0.141 bears/km² in the 20,404-km² primary zone and 0.026 bears/km² in the 4,299-km² secondary zone (Table 4). The estimated number of females in both primary and secondary zones in North Carolina, including GSMNP, was 2,983 (Table 4). Hunters reported an average kill of 453.3 females/year in combined primary and secondary estimation areas (2016–2018; North Carolina Wildlife Resources Commission 2020). Excluding bears in the North Carolina portion of GSMNP, which were not subjected to hunting, estimated female abundance in the primary and secondary zone was 2,582 (95% CI = 1,916–3,478), resulting in a mean annual harvest rate of 17.6% (Table 4).

To estimate abundance in South Carolina, we created a primary zone to better coincide with State Game Zone 1 and calculated density estimates based on estimates from the primary zone model parameters. Mean female density in South Carolina was 0.118 bears/km² in the 2,137-km² primary zone and 0.002 bears/km² in the 7,092-km² secondary zone (Table 4). The estimated number of adult females in the primary zone in South Carolina was 252 and in the secondary zone was 11, totaling 263 for all of western South Carolina (Table 4). Hunters reported an average of 44.3 females/year from 2016 to 2018 (SABBSG, unpublished data). Based on our estimated female abundance in the primary zone, the mean annual harvest rate was 17.6% (Table 4).

To estimate abundance in Tennessee, we slightly modified our primary zone to better coincide with State Hunt Zones 1, 2, and 3 (Tennessee Wildlife Resources Agency 2020b) and calculated density estimates from within that primary zone. Mean female density in Tennessee was 0.119 bears/km² in the 11,726-km² primary zone and 0.017 bears/km² in the 7,312-km² secondary zone. The estimated number of females in the primary and secondary zones in Tennessee, including GSMNP, was 1,522 (Table 4). Hunters in Tennessee reported an average harvest of 242.7 females/year in our evaluation area from 2016 to 2018 (SABBSG, unpublished data). Excluding bears in GSMNP, which were not exposed to hunting, our female abundance estimate was

1,063 (95% CI = 782–1,447), resulting in an average female harvest rate of 22.8% (Table 4).

DISCUSSION

Harvest is usually the primary mortality factor in hunted black bear populations, but harvest rates are rarely estimated across extensive areas because of the difficulty of obtaining reliable population abundance estimates. Perhaps the most intensive effort to do so was in Pennsylvania, USA, where hundreds of black bears were captured and tagged annually, and those tags recovered from hunters. Diefenbach et al. (2004) reported that during 1983–2001, the annual female harvest rate averaged 16.5% based on a sample of 2,658 captured bears. Tri et al. (2017) conducted an analysis of harvest rates of bears in urban-wildland settings in New Jersey, Pennsylvania, and West Virginia, USA, and documented annual harvest rates for bears of both sexes ranging from 0 to 26.2%. Based on a survey of resource managers across North America, Hristienko and McDonald (2007) concluded that black bear harvest rates >20% appeared to be

sustainable for bear populations in the eastern United States. Bunnell and Tait (1981) estimated the maximum mortality rate that could be sustained by black bear populations of both sexes, depending on natality and recruitment rates. Maximum mortality ranged from about 10–24%, with estimates of about 23% for bears with an age of primiparity of 3 and an average litter size of 2, which is generally consistent with bear demographics in the southern Appalachian highlands (Balkcom et al. 2019). Bunnell and Tait's (1981) sustainable mortality rate estimates, however, included all forms of mortality.

Our female harvest rate estimates ranged from 12.7% in northern Georgia to 22.8% in eastern Tennessee, though 95% confidence intervals overlapped among all states (Table 4). Based on bait-station survey data, bear abundance in the 4 states that we sampled generally showed a steady increase from 1983 to about 2009, then began to decline (SABBSG, unpublished data; Fig. 3). Although food supply and weather can affect bait-station surveys (Brongo et al. 2005, Clark et al. 2005), the index can be informative at broad spatial and temporal scales. We assumed constant N from 2016 to 2018, but bear population abundance may well have been declining

during and previous to those years, assuming the bait-station indices reflected true population densities. Regardless, those moderate harvest rates in Georgia would not seem to be adequate to have produced the population decline as suggested by the bait-station data. That inconsistency could, of course, be explained by a positive bias in our abundance estimates or low reporting rates by hunters. Bait-station indices for all 4 states in the region began to decline following a series of low regional hard mast indices from 2006 to 2009 (SABBSG, unpublished data; Fig. 3). Prolonged periods of mast scarcity can result in black bear reproductive failures and increased mortality rates (Pelton and van Manen 1996, Clark 2004, Clark et al. 2005). Higher than normal natural and harvest mortality and low recruitment rates for females as a result of poor mast availability could have triggered a regional population decline, perhaps exacerbated and prolonged by harvest; however, this explanation is speculative.

Although bait-station indices began to decline around 2009 (Fig. 3), conflict complaints and harvest numbers have continued to increase (Fig. 1). We suggest care in interpreting those numbers as being indicative of population trend. Reported conflicts can vary because of food, weather, human behavior, agency reporting protocols, and human population densities. Numbers of bears killed by hunters are also affected by food availability and weather but can be further compromised by incomplete reporting. Also, the relationship between harvest and hunter effort may change with animal abundance, with hunter effort increasing as game populations decrease (Bowyer et al. 1999, Schmidt et al. 2005).

The mean density in GSMNP was 0.349 female bears/km² (95% CI = 0.257–0.475) and the estimate of female bear abundance in the 2,103-km² park was 734 (95% CI = 540–997). That density estimate was 2.7 times higher than primary zone estimates outside the park (0.130 bears/km²) and likely reflected high quality habitat in GSMNP and protection from hunting. Braunstein et al. (2020) reported that radio-collared female bears routinely left park boundaries and ear-tagged bears from the park

Figure 3. Regional hard mast survey data and bait-station survey data for the 4-state southern Appalachian region (GA, NC, SC, TN, USA), 1981–2018 (Southern Appalachian Black Bear Study Group, unpublished data).

were routinely recovered in the harvest, which likely served as a reservoir and source of immigrants for harvest by hunters, particularly in Tennessee. The National Park made up a large portion of bear range in Tennessee and including all bears in GSMNP as available for harvest reduced the estimated harvest rate from 22.8% (95% CI = 16.8–31.1) to 15.9% (95% CI = 12.0–21.1). The true harvest rate likely lies somewhere between those 2 estimates.

Although we evaluated several land cover and land use covariates as they related to female density, only percent forest was supported (Table 2). We nevertheless report positive relationships between D and mean elevation ($\beta = 2.8$, 95% CI = 2.2–3.3) and distance to development ($\beta = 1.3$, 95% CI = 0.9–1.8), and negative relationships with percent shrub ($\beta = -66.6$, 95% CI = -71.7 to -61.5) and percent evergreen forest ($\beta = -1.9$, 95% CI = -3.3 to -0.5). Models with a behavioral response at specific traps (bk) on g_0 and σ were well supported based on AIC_c as were models with individual detection heterogeneity expressed as 2 finite mixtures (h2; Table 2). Harvest rates for females varied across the region and, although we included a model with state as a covariate for management differences across state boundaries, this model had several categorical variables and maximum likelihood estimation did not converge on a solution. Despite its simplicity, the percent forest covariate seemed to do a good job of reflecting female bear densities in the region. Densities were much lower in the secondary zone and GSMNP had the highest bear densities as expected.

About 11,496 traps would have been needed for our 66,678-km² study area based on non-spatially explicit capture-recapture methods evaluated by Settlage et al. (2008). In contrast, we were able to obtain reasonable population abundance and density estimates with only 888 hair traps (7.7% of the estimated non-spatial trap-site density) with spatially explicit capture-recapture methods, cluster sampling, and a large spatial extent (Howe et al. 2013, Clark 2019). Our large study area also facilitated pooling of data across jurisdictional boundaries to better estimate model parameters (e.g., g_0 and σ) and enabled costs to be shared by several state wildlife agencies, which illustrates the benefit of interagency collaboration.

Integrating spatially explicit capture-recapture methods with other data collected in the region on bears could lead to better understanding of relationships between environmental fluctuations and management actions on bear demography. Such ancillary data could be used to help inform spatially explicit population estimators during years when these more costly and labor-intensive methods cannot be conducted (Chandler and Clark 2014). Cluster sampling coupled with spatially explicit mark-recapture methods is a powerful strategy for estimation of population parameters for a variety of wildlife species that are managed across large spatial extents. Cluster sampling for spatially explicit population estimation could be adapted for other species from which hair (Morehouse and Boyce 2016), scat (Bozarth et al. 2015, Morin et al. 2018), muscle biopsies (Beausoleil et al. 2016), and camera data (Royle et al. 2011, Borchers et al. 2014) could be collected.

MANAGEMENT IMPLICATIONS

Harvest rates approached or exceeded a theoretical maximum in some jurisdictions and population trend data indicated population declines in most jurisdictions in recent years. Although this response to recently liberalized harvest regulations was not unexpected, continued monitoring of bear populations (e.g., annual bait-station surveys and periodic population estimation with spatially explicit mark-recapture methods) would help to ensure that population trajectories continue to be consistent with management goals. Likewise, continued monitoring of hard mast production would help managers evaluate the effects of mast failures on bear population trajectories as more years of data are collected. The SABBSSG proved to be an excellent mechanism for coordination of these monitoring activities.

ACKNOWLEDGMENTS

Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the United States Government. This study was made possible by the forethought and wisdom of previous bear managers to create the Tri-State Bear Study Group (later SABBSSG), which enabled us to share data and coordinate funding, field work, and data analysis across jurisdictions. We thank D. B. Gibbs and others at the Tennessee Wildlife Resources Agency for collecting and allowing access to the 2018 secondary zone hair data in Tennessee. We also thank A. D. Hammond, C. Olfenbuttel, and T. W. Waldrop for their assistance in the study design, planning, permitting, and field operations. The number of technicians and volunteers on this project is too long to list, but our gratitude is heartfelt for their long solitary hours working in extremely harsh conditions. A special thanks goes to S. Millman for his tireless efforts in the logistical planning and management of the field study. We are also indebted to the United States Forest Service, the National Park Service, numerous state parks, and countless private landowners for allowing access to their land. We thank D. Paetkau and the other professionals at WGI for genotyping advice and analysis. M. G. Efford was always available to answer our questions about secr and E. J. Howe assisted as well. We are indebted to the University of Tennessee's Fleet Management staff for facilitating the use of over 20 rental vehicles each field season. Implementing such a large study would not have been possible without the record keeping and administrative contributions of T. D. White. We are deeply grateful the Georgia Department of Natural Resources, North Carolina Wildlife Resources Commission, South Carolina Department of Natural Resources, Tennessee Wildlife Resources Agency, United States Forest Service, and USGS for funding this study.

ABSTRACT

Male targeted harvest regimes of carnivores are now widely accepted to result in increased sexually selected infanticide (SSI). Male targeted harvest regimes of males should therefore result in increased sexually segregated habitat use in infanticidal carnivores. We tested the effects of low and high levels of male hunting mortality and associated SSI on sexually segregated habitat use in mountain lions. The “no effect of hunting” hypothesis predicts that no sexual segregation would occur or that all female mountain lions would segregate from males because of sexual dimorphism. The “hunting effect” hypothesis predicts that females with kittens would segregate from younger immigrant males in the heavily hunted population during summer when kittens are vulnerable to SSI. We rejected the “no effect” hypothesis and accepted the “hunting effect” hypothesis for mountain lions. Females with kittens avoided immigrant males in the heavily hunted population during summer—others did not. This sexual segregation corresponded with females with kittens selecting for food-poor, high elevations in the heavily hunted population but not in the lightly hunted population. Avoidance of males and selection for high elevations resulted in prey switching by females with kittens from abundant primary prey in lower elevations to rare, sensitive and threatened secondary prey at higher elevations. It appears that remedial sport hunting of mountain lions to reduce predation on declining prey actually caused sexual segregation and increased predation on declining prey. We suggest that excess mortality of male carnivores could result in unanticipated cascade effects including sexual segregation and prey switching to declining prey.

1. Introduction

Sport hunting in a wide variety of male carnivores can induce sexually selected infanticide (SSI) by causing rapid turnover of breeding males (see Wielgus and Bunnell, 1994a, 2000; Wielgus et al., 2001, for North American grizzly bears *Ursus arctos*; Swenson et al., 1997; Swenson, 2003, for European brown bears *U. arctos*; Packer et al., 2009, 2011, for African lions *Panthera leo*; and Balme et al., 2012a, 2012b, for African leopards *Panthera pardus*). In our animal model (mountain lions, *Puma concolor*), high male mortality (35%) resulted in a shift in the sex/age structure towards numerous, younger, potentially infanticidal, immigrant males (Robinson et al., 2008). Lower male mortality (15%) resulted in less numerous, but older resident males (Cooley et al., 2009a). The higher male mortality corresponded with higher mortality rates of kittens (69% vs. 42%, Cooley et al., 2009b) and higher rates of plausible infanticide (27% vs. 0%, Wielgus et al., 2013).

Females should respond behaviorally to SSI by separating from and avoiding potentially infanticidal, immigrant males. For example, in a heavily hunted North American grizzly bear population (30% older male

mortality, Wielgus and Bunnell, 1994a), females with cubs segregated into high elevation, xeric, food-poor environments where the numerous younger immigrant males were rare (Wielgus and Bunnell, 1994b). In a nearby lightly hunted population (19% younger male mortality, Wielgus et al., 1994) females with cubs did not segregate from older resident males in food-rich environments (Wielgus and Bunnell, 1995). Those behavioral differences (sexual segregation) corresponded with reproductive strategies where the elasticity of cub survival was greater than the elasticity of litter size which maximized fitness (Wielgus and Bunnell, 2000, Wielgus et al., 2001). Steyaert et al. (2013) also found that European female brown bears with cubs in a heavily hunted population segregated into different habitats than males during the potentially infanticidal breeding season. However, those papers demonstrated sexually segregated differences in habitat use and selection for *U. arctos*, not avoidance of males per se. It is still possible, though highly unlikely, that those sexual differences in habitat use could have been due to intrinsic differences in habitat selection between the sexes (habitat segregation: Clutton-Brock et al., 1982, Villaret and Bon, 1995, Main and Coblentz, 1996, Conradt, 1999, Ruckstuhl and Neuhaus, 2005) not actual avoidance of males because of SSI (social segregation: Swenson, 2003, Rode et al., 2006).

In this paper, we compare sexually segregated spatial distribution in a lightly and heavily hunted population of another species (mountain

^{*} Corresponding author.

lions) to test for generality to other carnivores. We also directly test the social segregation hypothesis (females with cubs avoid immigrant males in a heavily hunted population but do not avoid resident males in a lightly hunted population) by examining differences in spatial distribution between reproductive classes. We use the same two study areas (northeastern Washington and central Washington) and same two heavily and lightly hunted mountain lion populations as extensively reported in Cooley et al. (2008), Robinson et al. (2008), Cooley et al. (2009a), Cooley et al. (2009b), White et al. (2011), and Wielgus et al. (2013)—to test if hunting has an effect on sexual segregation.

If sexual segregation were driven by intrinsic sexual differences in body size and energetics (hunting has no effect)—the habitat segregation hypothesis makes four basic predictions based on reproductive class, area, season, and their combined effects. 1) Reproductive classes: the higher energy demands of females with kittens should be more similar to larger, sexually dimorphic males than that for lone females (Ruckstuhl and Neuhaus, 2002), therefore sexual segregation should be less pronounced for females with kittens. 2) Areas: males in the lightly hunted area selected for larger prey (elk *Cervus elaphus* vs. mule deer *Odocoileus hemionus*) than females (White et al., 2011), but elk were not available in the heavily hunted area (Cooley et al., 2008, Wielgus et al., 2013)—therefore sexual segregation should be more pronounced in the lightly hunted area where sexually dimorphic use of prey was already apparent. Furthermore, home range size, male to male home range overlap, and female to female home range overlap were greater in the heavily hunted area (Maletzke, 2010)—so spatial sexual segregation should be less pronounced there because of greater shared area among conspecifics. 3) Seasons: spatial expansion of home range size occurred during summer and male to male and female to female home range overlaps increased with increasing home range size (Maletzke, 2010)—so spatial sexual segregation which is driven by landscape factors, rather than risk avoidance, should be less pronounced during summer because of greater shared area among conspecifics (Terborgh et al., 1999). 4) The additive effects of reproductive class, area, and season: sexual segregation should be most pronounced for solitary females in the lightly hunted area during winter and should be least pronounced for females with kittens in the heavily hunted area during summer.

If segregation was driven by social avoidance of males by females because of the threat of SSI (hunting has an effect) the reproductive class, area, and season predictions are exactly the opposite. 1) Reproductive classes: sexual segregation from males for females with kittens should be higher than for solitary females. 2) Areas: Sexual segregation should be more pronounced in the heavily hunted area because of the abundance of younger potentially infanticidal males. 3) Seasons: Goodrich et al. (2008) found that tiger (*Panthera tigris*) cubs were most vulnerable to infanticide during the first 6 months of life. Almost all mountain lion births occurred during the summer and all six cases of plausible infanticide within the heavily hunted area appeared to occur during the summer months (Cooley et al., 2009b)—so sexual segregation should be more pronounced during the summer. 4) Additive effects: sexual segregation should be most pronounced for females with kittens in the heavily hunted area during summer and should be least pronounced for solitary females in the lightly hunted area during winter.

2. Materials and methods

2.1. Study areas

The two areas selected for use in this study reflect different intensities of human hunting mortality on mountain lions (Fig. 1). The heavily hunted study area (HH) in northeastern Washington covered 1476 km². Hound hunting and boot hunting (incidental harvest of mountain lions while hunting deer or elk) were encouraged in the area to alleviate human–mountain lion conflicts (Lambert et al., 2006) and to relieve predation on declining mule deer (Robinson et al., 2002, 2008; Cooley et al., 2008). There was no established quota on harvest of male

mountain lions and bag limits were limited to one cougar per hunter per year. It is comprised of Northern Rocky Mountain Forest–Steppe–Coniferous Forest–Alpine Meadow (Bailey, 1995) and includes Washington Game Management unit 105. Elevations ranged from <400 m along the riverbanks, to >1400 m in montane forest. Precipitation ranges between 51 cm and 102 cm annually, falling mostly in the form of snow (Bailey, 1995). Tree and plant communities include ponderosa pine (*Pinus ponderosa*) on the lower elevation south and west facing slopes; western red cedar (*Thuja plicata*) in moist, lower elevation valleys; Douglas-fir (*Pseudotsuga menziesii*) interspersed throughout much of the mid elevations; and western larch (*Larix occidentalis*); subalpine fir (*Abies lasiocarpa*) and Engelmann spruce (*Picea engelmannii*) at higher elevations. Land use included recreation (mostly hunting), timber harvest, and cattle ranching. Carnivore species included mountain lions, black bears (*Ursus americanus*), bobcats (*Felis rufus*) and coyotes (*Canis latrans*). White-tailed deer (*Odocoileus virginianus*) and mule deer were the most common ungulates in the study area (Cooley et al., 2008). Elk, moose (*Alces alces*), and mountain goats (*Oreamnos americanus*) were very rare.

The lightly hunted study area (LH) encompasses the western half of Kittitas County in central Washington and covers 1652 km². There was no established quota on harvest of male mountain lions and bag limits were limited to one cougar per hunter per year. Hound hunting of mountain lion was prohibited during the period of the study although, “boot hunting” was allowed. It is classified as Northern Cascade Mixed Forest (Bailey, 1995) and includes Washington Game Management Units 335 (Teaaway) and 336 (Taneum). Ponderosa pine and Douglas fir communities were intermixed with agricultural lands in the lower elevations (550 m). Sub-alpine fir, Engelmann spruce, Pacific silver fir (*Abies amabilis*) and western hemlock (*Tsuga heterophylla*) dominated the mid and upper elevations (1550 m). The majority of precipitation falls during winter as snow; the average winter snowfall is 160 cm (Cooley et al., 2009a). Elk and mule deer are the most numerous ungulates. White-tailed deer are absent or extremely rare in the area. Other common carnivores include black bear, bobcat and coyote.

2.2. Demographic comparisons of heavily hunted (HH) and lightly hunted (LH) areas

The heavily hunted (HH) area had an overall hunting mortality rate of 0.24 and a male hunting mortality rate of 0.35. The survival-fecundity growth rate was 0.78, with a net immigration rate (mostly males) of 0.13—resulting in an overall observed growth rate of 0.91. Density was stable (at equilibrium) over 5 years at 3.46 mountain lions/100 km². The mean age of males was 24 months (Cooley et al., 2009b). The mean home range size of females was 240 km² and males was 752 km² (Maletzke, 2010). Six of 11 kitten deaths reported in Cooley et al. (2009b) were believed to have been caused by male mountain lions via infanticide.

The lightly hunted area (LH) had an overall hunting mortality rate of 0.11 and male hunting mortality rate of 0.16. The survival-fecundity growth rate was 1.10 with a net emigration rate of 0.12 (mostly males) resulting in an annual observed growth rate of 0.98. Density was stable over the period of the study at 3.62 mountain lions/100 km². The mean age of males was 41 months (Cooley et al., 2009b). The mean home range size of females was 199 km² and males was 348 km². Zero of five kitten deaths were reported in Cooley et al. (2009b) as infanticides although some may have occurred and not been detected.

2.3. Capturing and handling

All animals were handled in accordance with Washington State University Animal Care Permit #3133 and Animal Welfare Assurance Committee Permit A3485-01. Mountain lion captures were conducted during winters 2002–2008. The study areas were searched for tracks and hounds were released to tree mountain lions (Hornocker, 1970).

Fig. 1. Heavily hunted and lightly hunted study areas in Washington and British Columbia.

A dosage of 0.4 ml per 10 kg of body mass of ketamine hydrochloride (200 mg/ml) and xylazine hydrochloride (20 mg/ml) was injected into the hindquarter of treed mountain lions via a projectile dart (Ross and Jalkotzy, 1992). Mountain lions were fitted with Lotek GPS4400S collars (Lotek Wireless, Newmarket, Ontario, Canada), examined for sex, age, and condition, and released. Collars were programmed to attempt a location between four and six times per day. Animals were recaptured once per year (when possible) to assess condition and refit the collars with new batteries. For details see Cooley et al. (2009a) and Robinson et al. (2008).

2.4. Reproductive classes and seasons

Individual mountain lions were assigned to one of three reproductive classes: females with kittens (FK); solitary females (F) or independent males (M). Independent females were classified as “females with kittens” after kittens were discovered in the den. Females remained in that class as long as their kittens were alive accompanying the mother. Females with kittens reverted to “solitary females” if kittens died or dispersed. Many females transitioned between both classes during the course of the study. Independent males were those sexually mature animals that no longer accompanied their mothers. Winter was between November 1 and April 30 and summer was May 1 through October 31—to coincide with periods of snowfall and kitten vulnerability (Cooley et al., 2009b). More than 90% of kittens were born during the summer (Cooley et al., 2009b).

2.5. Sexual segregation

We first studied the three-dimensional home range overlap between the sexes and then further compared the selection of elevation between the sexes.

2.6. Utilization distribution overlap index

We first calculated 95% kernel density estimates using Hawth's Analysis Tools for ArcGIS (Beyer, 2004) to estimate summer and winter

home ranges for individuals in all reproductive classes. We then calculated seasonal utilization distribution overlap indices (UDOI-Fieberg and Kochanny, 2005) for adjacent male and female mountain lions showing at least 1% overlap of their home ranges during the study, using a script written for the R environment for statistical programming (R Development Core Team, 2009). 3-d utilization distribution overlap differs from 2-d home range overlap by including a temporal component to calculate the probability that two individuals used the same space (Fieberg and Kochanny, 2005). Index values range from 0.0 (no overlap) to 2.0 (complete overlap). All references in this study to UDOI are between females with kittens and males, and solitary females and males. We calculated the mean UDOI value for each female by summing the UDOI values of each overlapping male and dividing by the number of overlapping males (Maletzke, 2010). We tested for differences in mean UDOI values for reproductive class, area, season, and their interactions using factorial analysis of variance (ANOVA) and Tukey's Honestly Significant Test. We compared the additive effects of reproductive class, area, and season by constructing 95% confidence intervals around the mean UDOI for individuals within each class, area, and season combination.

2.7. Use versus availability of elevation

If segregation occurs at a finer (within home range) scale than the UDOI is able to detect, it may still be influenced by social or habitat factors *within* the home range (Neu et al., 1974). If such differences are occurring *within* home ranges, comparing UDOI values may fail to capture these fine scale differences if the variation occurs *within* the home range scale rather than at a landscape scale. Therefore, we also compared the use/availability of elevation (same as Wielgus and Bunnell, 1994b) by mountain lions in the heavily hunted population to that of the lightly hunted population to determine if segregation by elevation was occurring at the finer, within home range scale.

We compared the use of available elevation by FK, F and M within study areas and within seasons using Type II and Type III parametric ANOVA study designs (Thomas and Taylor, 1990). We also tested for differences in the distribution of used and available elevation using

non-parametric Kolmogorov–Smirnov tests. First, we calculated the availability of elevation for each individual using the mean of all 30 m × 30 m pixels contained within the 95% kernel density estimator home ranges calculated for use in the UDOI analysis. We then calculated use of elevation for each individual using the mean of all GPS point location coordinates for that individual. To determine if individuals were using elevation differently than was available to them (Type III; Thomas and Taylor, 1990, 2006), we used paired t-tests (SYSTAT) to test for differences in the mean elevation of used, versus available points of elevation for each individual.

Next, to determine if mean use was different than mean availability for each reproductive class, we calculated the means for all individuals within each reproductive class by study area and season and tested for differences in mean use and mean availability for reproductive classes (Type II; Thomas and Taylor, 1990) within each area and season using paired t-tests. To determine if the differences in use and availability within each reproductive class were different between reproductive classes, we used analysis of variance (Type II; Thomas and Taylor, 1990).

2.8. Kolmogorov–Smirnov tests

Last, because animal locations may be bimodal distributed with respect to elevation, we compared the actual distribution of points across the elevation gradient in the kernel home range with the available elevation. An individual may use elevation much higher, as well as much lower than the mean but have very little use near the mean (and therefore the mean may not accurately reflect the use of elevation within the home range). We calculated the mean difference in use versus availability for each reproductive class, by study area and season, and we tested for differences using the Kolmogorov–Smirnov test (SYSTAT). This was a non-parametric analog to our Type II ANOVA test.

3. Results

3.1. Utilization distribution overlap index

We captured, radio-monitored, and analyzed spatial data from 42 mountain lions in the two study areas: 22 total lions (13 males and 9 females) in the lightly hunted area and 20 total lions (7 males and 13 females) in the heavily hunted area. Each lion had 760 ± 418 (95% CI) GPS telemetry acquisitions per year.

UDOI differed among the main effects of reproductive class, area, and season in that order, but their interactions were not significant (Table 1). FK (UDOI = 0.25) overlapped less with males than F (UDOI = 0.47). The heavily hunted area (UDOI = 0.25) had less overlap with males than the lightly hunted area (UDOI = 0.46) and summer (UDOI = 0.26) had less overlap than winter (UDOI = 0.45).

The additive effects showed that the lowest UDOI with males was for FK in heavily hunted area during SUMMER (0.08) and the highest UDOI (0.66) was for F in lightly hunted area during WINTER (Fig. 2).

Table 1

Analysis of variance results for effect of reproductive class, area and season on Utilization Distribution Overlap Indices of mountain lions 2005–2008.

Source	Type III SS	Df	Mean squares	F-ratio	P

3.2. Use versus availability of elevation

In the lightly hunted area no reproductive classes used elevation differently from availability during summer, nor were any reproductive classes different from each other (Table 2). During winter, all reproductive classes used elevations lower than were available but no reproductive classes were different than any other.

In the heavily hunted area during summer, females with kittens selected for elevations + 31.15 m higher than available, solitary females used elevation at availability, and males selected for elevations – 38.76 m lower than availability (Table 2). The overall difference in use versus availability of elevations between females with kittens and males was 69.91 m. During winter, only males selected for lower elevation than availability (– 29.13 m) and there were no differences between reproductive classes (Table 2).

Results from the Kolmogorov–Smirnov tests showed similar but more conservative results. The only difference in use vs. availability using the Kolmogorov–Smirnov test was between females with kittens and males in the heavily hunted area during summer. (Table 3).

4. Discussion

Our results show that trophy hunting of male carnivores exacerbates sexual segregation in mountain lions because of SSI, as it does in North American grizzly bears (Wielgus and Bunnell, 1995) and appears to do in European brown bears (Steyaert et al., 2013). Our results do not support the “no effect of hunting” or habitat segregation hypothesis of sexual segregation in mountain lions because: 1) Sexual segregation (differences in UDOI and differences in selection of elevation) was less pronounced for solitary females with dissimilar energetic requirements than males and more pronounced for females with offspring with similar energetic requirements. 2) Sexual segregation was less pronounced in the lightly hunted area where sexually dimorphic prey use was already observed and was more pronounced in the heavily hunted area where intra-sexual spatial overlap and shared space was already greater. 3) Sexual segregation was less pronounced during winter and was more pronounced during the summer when intra-sexual spatial overlap and shared space was already higher. The increased overlap between reproductive classes during winter is similar to results from a mountain lion population in Wyoming where associations appeared to be driven by snow depth and prey distribution (Elbroch et al., 2014).

Our results support the “hunting effect” social segregation hypothesis of sexual segregation in mountain lions because females with offspring avoided males (lower UDOI) and selected for higher elevations than males, especially in the heavily hunted area (with more infanticidal immigrant males), and during the summer when kittens are more vulnerable to infanticide. Differences in UDOI were not apparent in either study area during winter, suggesting avoidance of males may be due to the higher vulnerability of offspring to infanticide when kittens are younger. Most kittens were born during summer months; as a result, the mean age of kittens was lower during summer than during winter. During winter their larger size and cumulative effect of learned behaviors may increase their chances of survival when encountering males. Goodrich et al. (2008) reported similar behavior in tigers where most incidents of infanticide occurred when tiger kittens were less than 6 months old. The same occurred for infanticide in European brown bears with younger cubs of the year (<1 year old) bearing the brunt (Swenson et al., 1997, 2001a, 2001b) and females with young cubs segregating from males (Steyaert et al., 2013). Sexual segregation in North American grizzly bears was also greatest during the summer for females with cubs of the year (Wielgus et al., 1994; Wielgus and Bunnell, 1995) and for black bears with cubs of the year (Collins et al., 2002).

The mean UDOI values for each reproductive class by season by area show a clear pattern supporting the main effects. First, females with kittens appear to have lower UDOI values than solitary females. Second,

Fig. 2. 95% CI of mean UDOI values of mountain lions in northeastern and South Central Cascades partitioned into groups by reproductive class, hunting regime and season. A value of 0.0 indicates no overlap and a value of 2.0 indicates complete overlap.

the heavily hunted area has lower UDOI than the lightly hunted and finally, summer showed lower UDOI values than winter. The additive effects showed that the lowest overlap was between females with kittens in the heavily hunted area during summer, and the greatest overlap was by females in the lightly hunted area during winter.

Differences in how females with kittens used elevation within their home ranges relative to males appeared very pronounced in the heavily hunted area; and no differences between these classes were evident in the lightly hunted area. In the heavily hunted area, females with kittens used elevation on average 31.15 m higher than was available to them; males used elevations 38.76 m lower than was available to them; solitary females used nearly exactly what was available (−3.19 m). The net difference in use of elevation versus availability between females with kittens and males during the summer in the heavily hunted was 69.91 m. The biological effect of 69.91 m can be compared to results from Husseman et al. (2003). They modeled differences in kill site attributes between wolves (*Canis lupus*) and mountain lions and found a mean difference in kill elevations between the species of 82 m (1688 m and 1608 m respectively). The difference in elevation observed

here for females with cubs and males is similar to that observed for two different species of predator.

These results are consistent with the observed differences in prey use by different reproductive classes in the heavily hunted area during summer. Females with kittens selected for low density, declining secondary prey (mule deer) at higher elevations during summer, but males and solitary females selected for high density, primary prey (white-tailed deer) at low elevations throughout the year (Keehner et al., unpublished results). Such prey switching from abundant to rare prey (all else being equal) runs counter to all standard energetic models of rational predator/prey dynamics (Case, 2000, Sinclair et al., 2006).

These results and the results of Robinson et al. (2008), Cooley et al. (2009a, 2009b), and Maletzke (2010), indicate that spatial segregation between reproductive classes of mountain lion is occurring in the heavily hunted study area and may be the result of heavy male harvest of mountain lions. Furthermore, this segregation appears to be influencing predator selection for low density, declining, mule deer (Robinson et al., 2002; Cooley et al., 2008; Keehner et al., unpublished results). For yet another example, declines in the last remaining threatened Selkirk Mountain caribou (*Rangifer tarandus*) population in the lower US (Wittmer et al., 2005) also appears due to social segregation and prey switching by female mountain lions. In that case, very heavy hunting of males (66%, Lambert et al., 2006) corresponds with female use of high elevation caribou range and male use of low elevation white-tailed deer range (Wielgus, unpublished results). It appears that hunting of mountain lions to reduce predation on sensitive mule deer and

threatened mountain caribou may have actually precipitated and caused the mule deer and caribou declines.

5. Conclusion

So far, the unanticipated cascade effects of male trophy hunting in mountain lions includes: 1) female mountain lion population decline (Lambert et al., 2006, Robinson et al., 2008, Cooley et al., 2009b, Wielgus et al., 2013), 2) increased sexual segregation (this paper), and 3) prey switching to declining secondary prey (Keehner et al., unpublished results, Wielgus, unpublished results). Similarly, Davidson et al., 2011 found socio-spatial behavior in African lions (*P. leo*) was negatively affected by trophy hunting in Africa. Johansson et al., 2015 found that retaliatory killing of snow leopards (*Panthera uncia*) may disproportionately increase male snow leopard mortality as male snow leopards are more likely to prey upon domestic livestock than females or young males. Historically, carnivore management has seemingly concluded that the removal of males from the population is simply compensatory in nature. Recent studies have demonstrated very clearly, that the numerical response of carnivore populations is not the only consideration managers should take into account when setting hunting seasons, methods, bag-limits or quotas. Socio-spatial behaviors, including the effects of segregation also affect valuable prey species. We encourage others to conduct similar studies in other potentially infanticidal carnivores such as grizzly bears, brown bears, black bears, leopards, jaguars, and tigers to see if adult male mortality has similar negative effects worldwide.

ABSTRACT

Human development and climate change are two stressors that threaten numerous wildlife populations, and their combined effects are likely to be most pronounced along the human development-wildland interface where changes in both natural and anthropogenic conditions interact to affect wildlife. To better understand the compounding influence of these stressors, we investigated the effects of a climate-induced natural food shortage on the dynamics of a black bear population in the vicinity of Durango, Colorado. We integrated 4 years of DNA-based capture-mark-recapture data with GPS-based telemetry data to evaluate the combined effects of human development and the food shortage on the abundance, population growth rate, and spatial distribution of female black bears. We documented a 57% decline in female bear abundance immediately following the natural food shortage coinciding with an increase in human-caused bear mortality (e.g., vehicle collisions, harvest and lethal removals) primarily in developed areas. We also detected a change in the spatial distribution of female bears with fewer bears occurring near human development in years immediately following the food shortage, likely as a consequence of high mortality near human infrastructure during the food shortage. Given expected future increases in human development and climate-induced food shortages, we expect that bear dynamics may be increasingly influenced by human-caused mortality, which will be difficult to detect with current management practices. To ensure long-term sustainability of bear populations, we recommend that wildlife agencies invest in monitoring programs that can accurately track bear populations, incorporate non-harvest human-caused mortality into management models, and work to reduce human-caused mortality, particularly in years with natural food shortages.

1. Introduction

Human development and climate change are two important stressors threatening global biodiversity (Bellard et al., 2012; Newbold et al., 2015). Expanding human development and infrastructure affect wildlife by eliminating habitat (Theobald, 2010), fragmenting and degrading existing habitat (Riitters et al., 2009), and increasing human disturbance (Trombulak and Frissell, 2000; Hansen et al., 2005), impacts which have been shown to displace wildlife (Vogel, 1989; Sawyer et al., 2006), affect movement behavior (Hurst and Porter, 2008; Cushman and Lewis, 2010), reduce demographic rates (Hansen et al., 2005), and contribute to population declines (Sorensen et al., 2008). Climate change affects wildlife by shifting long-term averages of climatic variables (e.g., warmer overall temperatures, earlier growing

season) and increasing the frequency and intensity of extreme climatic events (e.g., droughts, floods; Stocker et al., 2013), which all can have substantial effects on animal behavior (Wong and Candolin, 2015), physiology (Vázquez et al., 2015), distributions (Chen et al., 2011), and population dynamics (Koenig and Liebhold, 2016).

Recent research efforts have increasingly focused on understanding the cumulative and interactive effects of multiple stressors on wildlife populations as investigators have recognized the diverse pressures influencing animals and the potential for detrimental additive or synergistic effects (Brook et al., 2008; Mantyka-Pringle et al., 2012; Côté et al., 2016). Such interactions are likely to be particularly pronounced along the human development-wildland interface where multiple stressors can converge and have compounding impacts on wildlife populations. Animals living along the development-wildland interface

must contend with climate change-induced stressors in the natural environment such as shifts in vegetative phenology (Post and Forchhammer, 2008; Monteith et al., 2011), altered weather patterns (Rodenhouse et al., 2009; Skagen and Adams, 2012), and increased frequency of extreme climatic events (Altwegg et al., 2006; Boersma and Rebstock, 2014), while also coping with development-induced habitat loss and fragmentation, and increased exposure to disease, pollution, and human-caused mortality (McCleery et al., 2014). For example, climate-induced declines in sea-ice have reduced foraging opportunities for some polar bears (*Ursus maritimus*), and have forced them to reside on land during summer months. While this shift to land has been associated with reduced body condition of bears, it has also been accompanied by increases in conflicts with people (Stirling and Derocher, 2012), which can result in higher rates of human-caused mortality.

The compounding effects of multiple stressors along the human development-wildland interface are particularly concerning for the American black bear (*Ursus americanus*). Black bear behavior and demography are strongly tied to climate-induced variation in natural vegetative foods (Reynolds-Hogland et al., 2007; Baruch-Mordo et al., 2014; Johnson et al., 2015), and extreme weather events can cause seasonal food shortages which have been associated with reduced reproduction (Rogers, 1987a; Elowe and Dodge, 1989) and cub survival (Rogers, 1987a; Obbard and Howe, 2008). However, such events can also elevate levels of human-bear conflicts and human-caused mortalities (Zack et al., 2003; Baruch-Mordo et al., 2014) as bears increase their use of areas of human development in search of alternative food resources (Johnson et al., 2015). Because bear populations occurring along the human development-wildland interface are subject to the combined effects of climate-induced food shortages and increased human-caused mortality (e.g., vehicle collisions, lethal management removals, and illegal kills), their populations may be particularly susceptible to decline (Lewis et al., 2014). Improving our understanding of how multiple stressors drive black bear population dynamics is critical for developing future management policies that will ensure the sustainability of bear populations as changes in climate and land use continue.

We investigated the combined effects of human development and a climate-induced natural food failure on a black bear population located near the city of Durango in southwestern Colorado. In 2012, our study area experienced a late-spring hard freeze (Peterson, 2013; Rice et al., 2014) which caused a widespread natural food shortage for black bears in the region. Johnson et al. (2015) found that, under those conditions, black bears increased their use of human development to obtain anthropogenic resources for subsidy, a behavioral shift that had unknown consequences on the bear population. Our objective was to evaluate the effects of human development and the food shortage on the population of bears in our study area based on the hypothesis that combination of those stressors would result in a substantial population decline. We integrated spatial capture-recapture data and GPS collar data to quantify the abundance, density, and population growth rate of bears before and after the food shortage along the development-wildland interface. In addition, we used our integrated spatial capture-recapture models to investigate the influence of human development on the distribution of bears on the landscape (2nd order selection; Johnson, 1980) before and after the food failure. Our analysis provides important insight about the combined effects of multiple stressors facing black bear populations along the development-wildland interface, with key implications for bear management and conservation.

2. Study area

Our study area (Fig. 1) was located in southwestern Colorado and contained the city of Durango, Colorado (37.2753°N, 107.8801°W). Durango (~18,000 residents; <https://www.census.gov/quickfacts/>) is surrounded by mountainous terrain ranging in elevation from 1930 to

3600 m, and is generally characterized as having mild winters and warm summers that experience monsoon rains. Vegetation in the region is dominated by ponderosa pine (*Pinus ponderosa*), aspen (*Populus tremuloides*), pinyon pine (*Pinus edulis*), juniper (*Juniperus* spp.), mountain shrubs (*Prunus virginiana*, *Amelanchier alnifolia*, etc.) and agriculture. Agriculture in the region is primarily irrigated pasture for grazing livestock, which provides negligible food resources or cover habitat for black bears. Durango is largely surrounded by public land managed by the San Juan National Forest, Bureau of Land Management (BLM), Colorado Parks and Wildlife (CPW), La Plata County and the City of Durango.

3. Methods

3.1. General approach

To estimate population parameters for bears before and after the food shortage, we combined DNA-based spatial capture-recapture (SCR) data with GPS-telemetry based resource selection data into a single integrated spatial capture-recapture (ISCR) analysis. We limited our analysis to female black bears because we had reliable DNA and telemetry data for this segment of the population and because female demography is the key to understanding changes in the population dynamics of bears (Freedman et al., 2003; Beston, 2011). We assumed our estimates of demographic parameters applied only to the population of bears ≥ 1 year old because bears < 1 year old are unlikely to be detected by the sampling methods we used (Drewry et al., 2013; Laufenberg et al., 2016). Our approach was organized into a 2-stage analysis. In the first stage, we used GPS data and resource selection function (RSF) models to identify important 3rd-order resource selection covariates (within the home-range; Johnson, 1980) that were then used in the second stage. In the second stage, we integrated GPS and SCR data into a single model that allowed us to estimate abundance, density, detection probabilities, 3rd-order resource selection coefficients for habitat covariates identified in the first analysis, coefficients relating habitat covariates to the distribution of bears across the landscape (2nd-order selection; Johnson, 1980), and relative variable importance measures for 2nd-order habitat covariates. We obtained productivity data on important black bear foods collected during our study to characterize the natural food shortage caused by the late-spring freeze in 2012. We also obtained records of observed bear mortalities collected by CPW within our study area to use as an index of annual human-caused mortality during before and after the food shortage.

3.2. Data sources

3.2.1. Non-invasive DNA data

We used non-invasive hair sampling methods to obtain unique, multilocus genotypes for individual bears, determine individual identities, and record capture histories for capture-mark-recapture analysis (Woods et al., 1999). Each year from 2011 to 2014 we constructed an array of baited, barbed-wire enclosures (hereafter referred to as hair snares) from which we collected hair samples over multiple survey occasions. Hair snare locations were based on a regular 6×6 grid pattern with the grid-cell size set at 4×4 km. Each cell contained 1 hair snare consisting of a single strand of 4-point barbed wire stretched around and attached to ≥ 3 trees at 50 cm above ground and enclosing an area 6–10 m in diameter. We baited each hair snare with liquid scent applied to burlap hung in a tree approximately 3 m above ground and to an imitation “cache” of woody debris constructed at the center of the wire enclosure. Scent bait consisted of decomposing fish liquids, various commercial bear scents, and decomposing road-killed deer liquids. Following construction, hair snares were baited and subsequently checked every 7 days for 6 consecutive weeks each year from approximately the second week of June through the last week of July. Prior to initial baiting and after subsequent sample collections, we heat-

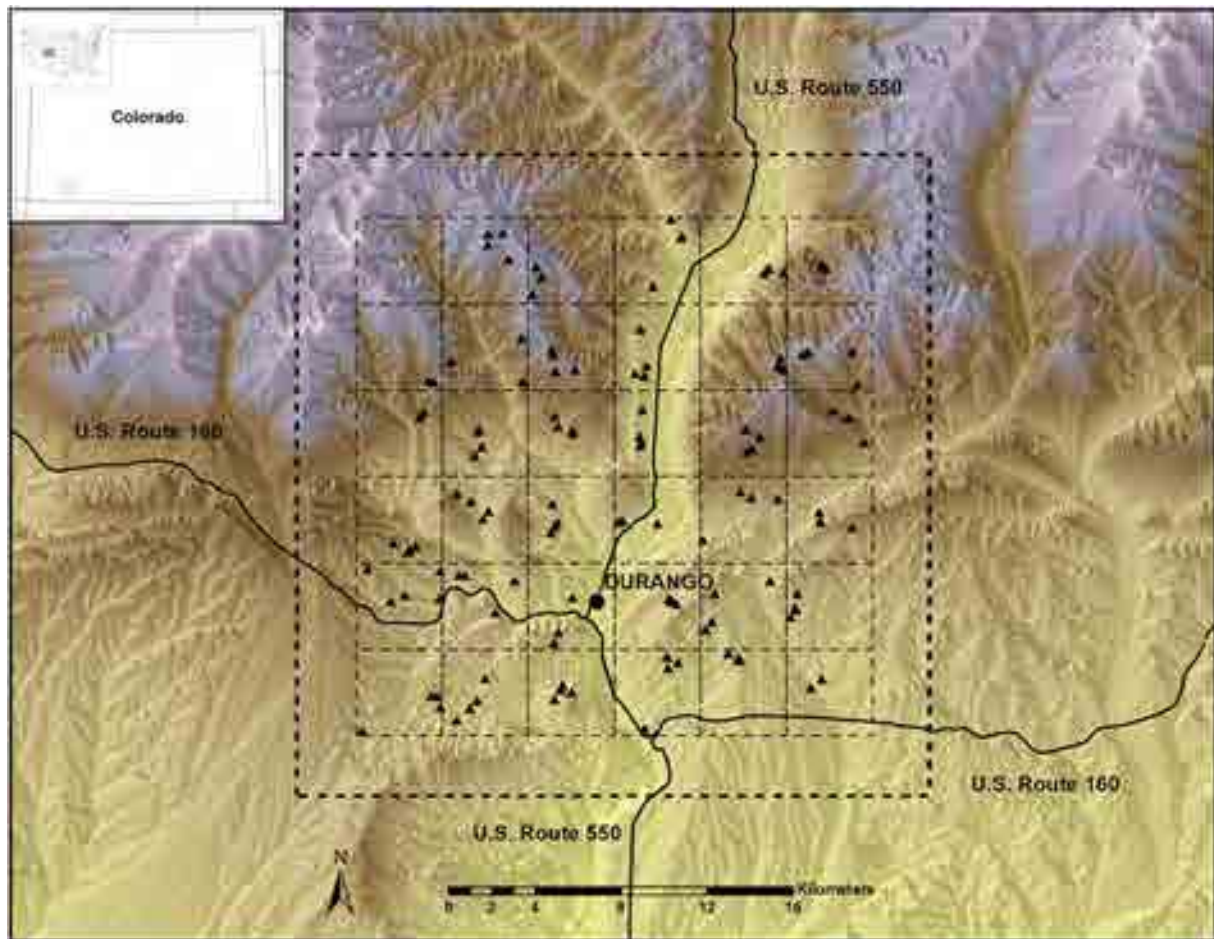

Fig. 1. Map of the study area showing the noninvasive sampling grid (thin dashed lines), hair snare locations (filled triangles) from 2011 to 2014, and state-space extent (thick dashed lines) in southwestern Colorado, USA near the city of Durango (filled circle). Major highways represented by solid lines. A single hair snare was operated per cell each year and the location of most snares changed across years resulting in multiple symbols per cell.

sterilized the barbed wire with a handheld lighter to prevent sample contamination between collection periods.

We submitted all samples to Wildlife Genetics International, Inc. (WGI; Nelson, BC, Canada) for DNA extraction and microsatellite genotyping following standard protocols (Woods et al., 1999; Paetkau, 2003; Roon et al., 2005). We selected 8 microsatellite markers (G10J, G10L, G10B, G1D, G10H, G10M, G10U, and MU59) that, when combined with a sex marker, provided sufficient power to reliably differentiate unique genotypes and identify individual black bears (Paetkau, 2003).

3.2.2. GPS-collar data

We captured black bears between May and September 2011–2014 within approximately 10 km of Durango using cage traps and Aldrich foot snares (Jonkel, 1993) following protocols described in Colorado Parks and Wildlife Animal Care and Use Protocol #01-2011. Adult female bears estimated to be ≥ 3 years old were immobilized and fitted with Vectronics Globstar collars (Vectronic Aerospace GmbH, Berlin). The collars were programmed to collect hourly GPS locations and were maintained during annual winter den visits so that individuals were continuously monitored until death or the collar malfunctioned. We only used GPS locations collected during the same period that hair-snare operations occurred to ensure that our SCR and GPS data sets were temporally matched for our joint analysis.

3.2.3. Mortality data

We used reports of bear mortalities opportunistically collected by

CPW from 2007 to 2014 to calculate annual counts of cause-specific mortalities that occurred within our study area. We classified mortalities into 3 cause-specific categories (vehicle, harvest, and lethal management removal) and 1 “other” category (e.g., electrocution, natural, unknown). We lacked the data to correct counts for imperfect detection and, thus, consider them a relative index of different sources of mortality rather than measures of true mortality rates.

3.2.4. Natural food data

We used productivity indices of 5 hard and soft mast-producing species (Gambel oak [*Quercus gambelii*], chokecherry [*Prunus virginiana*], crabapple [*Malus* spp.], serviceberry [*Amelanchier alnifolia*], and pinyon pine [*Pinus edulis*]) important to black bears in our study area to characterize annual natural food conditions. Indices were derived from bi-weekly surveys conducted along 15 transects each year during the months of August and September (for details see Johnson et al., 2017). For each transect, the possible range of values for each species was 0 to 100 with 0 indicating no mast detected, and 100 indicating that all plants observed had abundant mast. Based on the maximum score for each mast species on each transect across the sampling period, we calculated the annual median value of mast available for each species.

3.3. Data analysis

3.3.1. RSF variable selection

We developed an RSF model of space use that was later embedded into our ISCR model to effectively scale detection probability as a

Fig. 2. Summary of DNA-based capture-mark-recapture data for female American black bears collected in southwestern Colorado, USA from 2011 to 2014. Annual number of unique bears identified are represented by dark gray columns and total number of annual detections are represented by light gray columns. Italicized values are annual proportions of unique females detected more than once.

function of distance between a hair snare and animal activity centers *and* as a function of 3rd-order resource selection. We used a standard RSF model based on a multinomial formulation of a spatial point process model for discretized space (i.e., raster data) and extended to account for resource availability as a function of distance from animal activity centers (Johnson et al., 2008; Forester et al., 2009; Royle et al., 2013). This formulation conditions on the total number of telemetry locations for each bear which is a fixed component of study design based on a known frequency for collecting locations. We assumed that missing GPS locations were randomly distributed and chose not to explicitly model them given our average fix success rate across collared female bears was high ($\bar{x} = 0.92$). Formally, our model of space use for an individual was defined as:

$$\pi(\mathbf{x} | \mathbf{s}) = \frac{\exp(-\alpha_1 d(\mathbf{x}, \mathbf{s})^2 + \alpha \mathbf{z}(\mathbf{x}))}{\sum_{\mathbf{x}} \exp(-\alpha_1 d(\mathbf{x}, \mathbf{s})^2 + \alpha \mathbf{z}(\mathbf{x}))},$$

where $\pi(\mathbf{x} | \mathbf{s})$ is the probability of an animal using a raster pixel located at center coordinates \mathbf{x} given that animal's activity center located at coordinates \mathbf{s} , $\alpha_1 = 1/(2\sigma^2)$ describes the rate of decrease in probability of use as a function of distance in terms of a scale parameter σ , $d(\mathbf{x}, \mathbf{s})^2$ is the squared distance between a raster pixel and activity center, and α is a vector of regression coefficients that describes the effects that covariate values $\mathbf{z}(\mathbf{x})$ have on the probability of use.

We fit all possible additive combinations of 14 candidate RSF covariates (i.e., percent agriculture, aspen, conifer, meadow, oak shrub, pinyon-juniper association, riparian, shrub, and subalpine, elevation, slope, terrain ruggedness, and distance to drainage; for more detailed descriptions of resource selection covariates see Supplementary material 'Spatial Covariate Descriptions') to year-specific GPS data sets. We included a quadratic term for elevation in any model that contained elevation as a main effect, as bears are known to select for intermediate elevations within the study area (Johnson et al., 2015). The final model set contained 16,383 covariate models and was balanced with respect to each covariate occurring in an equal number of models. We used a maximum likelihood approach in R (v3.2.1, R Core Team, 2015) based on code adapted from Royle et al. (2013) to fit RSF models and obtain

estimates of model coefficients and variable importance. We ranked models using Akaike's Information Criterion corrected for small sample sizes (AICc; Burnham and Anderson, 2002) and calculated model weights to estimate variable importance. For each covariate, we summed AICc model weights for all models in which the covariate of interest occurred and retained only those covariates that had cumulative weights ≥ 0.5 for subsequent analyses (Barbieri and Berger, 2004).

3.3.2. Integrated spatial capture-recapture analysis

We used SCR models extended by Royle et al. (2013) to account for the effects that heterogeneous space use has on the detection process (i.e., allowing non-circular home ranges) by explicitly modeling 3rd-order resource selection. A common approach to modeling the spatial distribution of animals in SCR models is to use a homogeneous Poisson point process model that assumes constant population density across the landscape. However, we were interested in how the distribution of female black bears across the landscape was related to habitat covariates, particularly human development, and whether those relationships changed in response to the food shortage. Therefore, we used an inhomogeneous Poisson (IP) point process model to relate habitat characteristics to black bear density (2nd-order selection). Because our habitat covariates for density were derived in discretized space (i.e., raster format), we formulated our IP model using a multinomial distribution conditional on total population size (N) for the entire state space to describe pixel-specific abundance (N_m) as a function of covariates (Royle et al., 2013). Pixel-specific abundance was linearly related to habitat covariates through the use of a log-link function and estimated regression coefficients (β). We modeled bear density as a function of human development (DEVELOPMENT), elevation (ELEVATION), forest cover (FOREST), and stream density (STREAMS), which are similar to covariates important to predicting black bear densities in other studies (Evans et al., 2017; Sun et al., 2017; for more detailed descriptions of density covariates see Supplementary material 'Spatial Covariate Descriptions'). We fit all possible additive combinations of the 4 candidate density covariates and a constant density model (CONSTANT) to each year of data. We included a quadratic term for ELEVATION in any model that contained that covariate as a main effect. The final model set contained 16 density models and was balanced with respect to each covariate occurring in an equal number of models.

The detection model governs the observation process that produces SCR data, and includes a spatial component that scales detection probabilities as a function of space use conditional on the location of an animal's activity center. Under this formulation, space use and, thus, detection probability is modeled as a function of distance between a hair snare and an animal activity center controlled by a spatial scale parameter (σ) and as a function of resource selection coefficients (α). Following Royle et al. (2013), we assumed our SCR data was a random subset of use locations (e.g., GPS) "thinned" by the sampling effectiveness of the hair snare. We calculated year-specific detection probabilities, but assumed that the detection probability did not vary across occasions within a year (e.g., time effects) or was influenced by a behavioral response to bait because we used liquid lures designed to stimulate interest yet offer no food reward that would increase the likelihood of a bear revisiting a specific site. We also did not consider modeling additional sources of individual heterogeneity in detection probability because individual-level covariates were not available for bears only detected by hair snares and relatively small sample sizes precluded the use of latent heterogeneity models (e.g., finite mixtures, logit-normal).

To integrate our GPS data into our SCR analysis, we combined the likelihoods for the SCR model and the RSF model into a single analysis. Formally, we specified our ISCR model as a joint likelihood for the 2 data sets (i.e., SCR and GPS) assuming complete independence between data sets (Royle et al., 2013). Because both likelihoods contain the same model parameters governing space use (i.e., σ , α), information on resource selection and home range scale is shared between the two data

Fig. 3. Annual model-averaged parameter estimates from integrated spatial capture-recapture analyses using capture-recapture and GPS-telemetry data for female American black bears in southwestern Colorado from 2011 to 2014. Annual parameter estimates are abundance (panel A), realized population growth rate (panel B), population-level detection probability (panel C), and spatial scale of movement (panel D).

sets, allowing them to jointly estimate model parameters with improved precision. Understanding spatial patterns of resource selection, in turn, improved inferences about spatial heterogeneity in detection probabilities which then improved inferences for the point process governing estimates of abundance and spatial variation in density. Furthermore, integrating telemetry can greatly improve estimation of σ , a key detection model parameter in SCR models. As Royle et al. (2013) found, telemetry data is particularly useful for estimating σ when SCR data is sparse, which we anticipated was the case for our SCR data set.

We used a maximum likelihood approach in R based on code from Royle et al. (2013) to fit our ISCR models to each year of SCR-GPS data. We defined our state space by buffering our array of hair snares by 3 km which corresponded to a distance equivalent to $2 \times \sigma$; a distance that ensured the extent of our state space included the activity centers of all bears with access to the hair snare array (Fig. 1). The final state space had an area of 841 km² which we also used to define the extent of our habitat covariate rasters for modeling space use and density. We ranked models using AICc and calculated model weights for model averaging. By fitting our model set to each year of data independently, we were able to obtain year-specific model-averaged estimates of abundance and density. We derived realized population growth rates (λ) from our estimates of abundance and calculated associated sampling variances using the delta method (Powell, 2007). We derived year-specific model-averaged estimates of population-level detection probability (p) which we defined as the probability of a bear being detected at ≥ 1 hair snare in a given week. We used parametric bootstrapping to calculate

sampling variances for p . Additionally, we obtained year-specific estimates of relative importance for habitat covariates in our density analysis and produced model-averaged expected-density surfaces that provided inference on how bear distribution changed within the study area over time.

4. Results

We collected 2556 hair samples between 2011 and 2014. A total of 873 were excluded due to insufficient material ($n = 840$) or being hair from other species ($n = 33$). Of the remaining 1683 samples, 423 failed to produce reliable genotypes and 2 were classified as samples containing hair from ≥ 1 bear. The final data set contained 1258 successfully genotyped samples corresponding to a genotyping success rate of 74.7%. We identified a total of 138 unique female bears across all years with year-specific counts of unique females ranging from 41 to 61 (Fig. 2). We considered all genotyped samples for an individual collected at a given trap during a given sampling occasion to represent a single detection event. Pooling samples in this fashion resulted in year-specific SCR data sets containing counts of weekly detection events (y_{ij}) indexed by individual (i) and trap (j). The total number of detections for all years was 381 with annual totals of detections ranging from 84 to 113 and annual proportion of females detected more than once ranging from 0.27 in 2012 to 0.54 in 2014 (Fig. 2). The annual average number of sampling occasions during which females were detected ranged from 1.4 (SD = 0.7) in 2012 to 2.0 (SD = 1.3) in 2013 (Supplementary

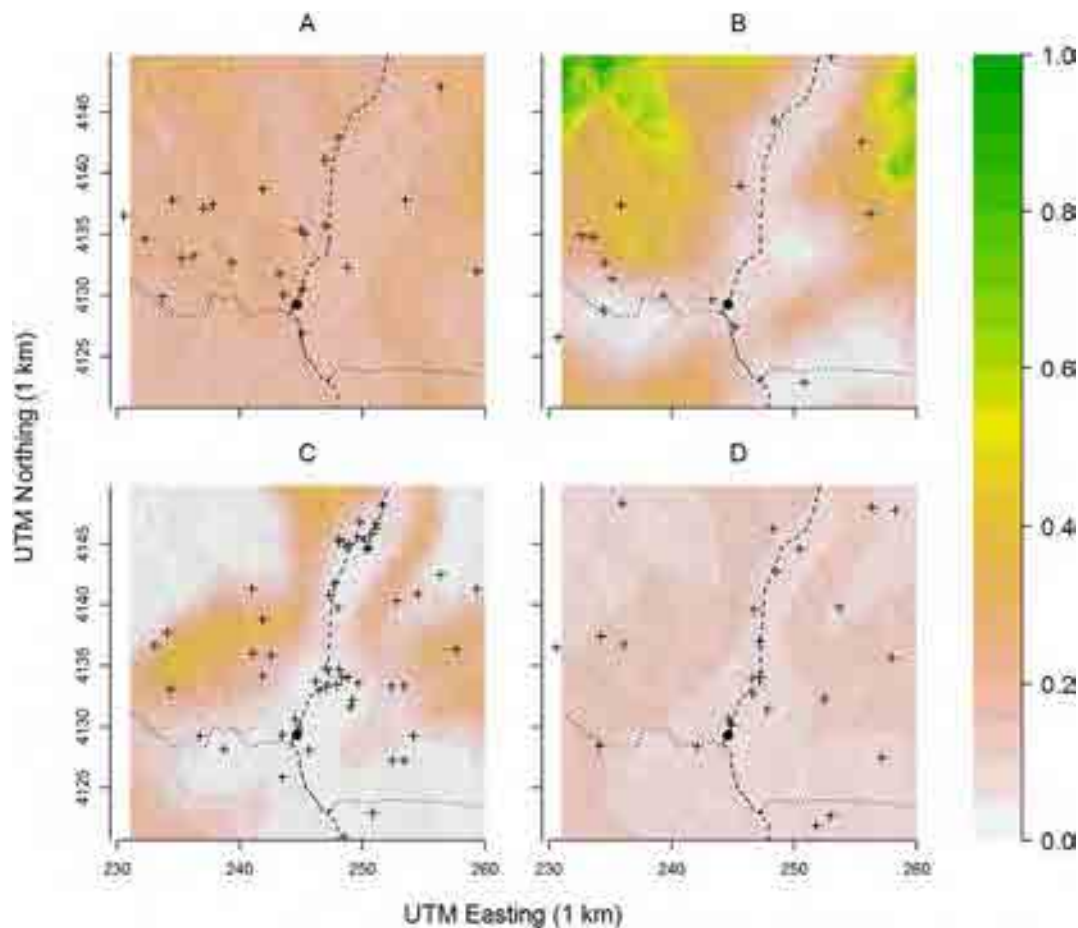

Fig. 4. Annual model-averaged predicted density (female bears/km²) surfaces for integrated spatial capture-recapture analyses using DNA-based capture-recapture and GPS-telemetry data for female American black bears in southwestern Colorado from 2011 to 2014. Panels A–D correspond to years 2011–2014 and the city of Durango, Colorado is represented by the filled circle. Locations of reported mortalities that occurred during the 12 months prior to each year of hair sample collection (e.g., 9 June 2012 to 9 June 2013 for panel C) represented by + symbols. material Table S1) and the annual average number of hair snares at which females were detected was 1.10 (SD = 0.3–0.4) in 2011, 2012, and 2014 and was 1.22 (SD = 0.55) in 2013 (Supplementary material Table S1).

We collected a total of 80,081 successful GPS locations from 45 unique female bears during annual hair-snare periods conducted from 2011 to 2014: 7451 locations in 2011 (10 bears), 23,476 in 2012 (27 bears), 22,423 in 2013 (23 bears), and 26,734 in 2014 (27 bears). The annual mean number of locations per female bear ranged from 745.1 (SD = 202.3) in 2011 to 990.1 (SD = 166.4) in 2014.

The number of RSF covariates identified as important (i.e., cumulative AICc weights > 0.50) in our first analysis stage and retained for the ISCR analysis varied across years from 13 to 15. Of the 15 possible covariates tested, distance-to-drainage was dropped in 2011, shrub and subalpine variables were dropped in 2012, and oak shrub and subalpine were dropped in 2013.

We estimated female abundance to be 175.6 (SE = 24.7) in 2011, 203.2 (SE = 43.0) in 2012, 86.7 (SE = 10.4) in 2013, and 82.4 (SE = 12.1) in 2014 (Fig. 3A, Supplementary material Table S2), exhibiting a marked population decline between 2012 and 2013 when the natural food shortage occurred. This corresponded to a rate of population change (λ) of 0.43 (SE = 0.05; Fig. 3B), which was significantly different (i.e., non-overlapping CIs) than λ estimates before and after the food shortage. Density estimates for the 841-km² state space followed the same temporal patterns as abundance and ranged from a high of 0.24 (SE = 0.05) female bears/km² in 2012 to a low of 0.10 (SE = 0.01) female bears/km² in 2014 (Supplementary material Table

S2). Year-specific model-averaged estimates of detection probability (p) ranged from 0.07 (SE = 0.01) in 2012 to 0.18 (SE = 0.01) in 2013 (Fig. 3C, Supplementary material Table S2). Annual model-averaged estimates of the spatial scale of movement parameter (σ) ranged from 1.25 km (SE = 0.01) in 2011 to 1.75 km (SE = 0.01) in 2014 (Fig. 3D, Supplementary material Table S2).

Model selection uncertainty was high with no single model attaining an AICc weight > 0.50 in any year (Supplementary material Tables S3–S6). Constant density models were most supported in 2011 and 2014, whereas more complex models with multiple covariates were most supported in 2012 and 2013 suggesting greater heterogeneity in the spatial distribution of female bears in those years (Fig. 4). Using a cumulative weight threshold of 0.5 to classify a covariate as an important predictor of density, DEVELOPMENT and STREAMS were important in 2012 (Fig. 5) when bear density was lower in areas of denser human development and higher in areas with greater stream densities (Fig. 4), and DEVELOPMENT and ELEVATION were important in 2013 (Fig. 5) when density was also lower in developed areas and higher in mid-elevation areas (Fig. 4). In general, during all years, bear density was lower in developed areas than undeveloped areas; however, this pattern was particularly notable in 2013 when developed areas were nearly devoid of female bears (Fig. 5).

Between 2007 and 2014, we obtained 206 bear mortality records opportunistically collected within our study area. Annual total counts ranged from 11 in 2009 to 54 in 2012, the latter being a 3-fold increase over the 5-year average prior to the food shortage in 2012 (\bar{x} = 20.0 [SD = 7.2]; Fig. 6). In 2012, mortalities caused by vehicle collisions

Fig. 5. Importance measures of covariates based on cumulative AICc model weights for integrated spatial capture-recapture analyses using capture-recapture and GPS-telemetry data for female American black bears in southwestern Colorado from 2011 to 2014. increased over 4-fold from the 5-year average of 3.4 (SD = 3.4) to 16 and 2 other human-caused sources, hunter harvest and lethal conflict removals, approximately doubled (Fig. 6).

Indices of natural foods available to bears were highly variable among years within species with species-specific CV values ranging from 0.8 to 1.4 (Fig. 7). Of the 5 mast species included in the natural food index surveys, 4 completely failed (i.e., index value = 0) to produce mast in 2012 (Fig. 7). Although no species completely failed in 2013 after the primary food shortage, productivity for 4 species remained below the mean value observed during the study indicating a possible residual climatic effect on bear foods from the previous year (Fig. 7).

5. Discussion

Our results provide evidence that human development can compound the effects of a climate-induced food shortage to significantly reduce a black bear population. Previous studies have found that food

shortages are often associated with reduced recruitment in black bears (Rogers, 1987a; Elowe and Dodge, 1989; Obbard and Howe, 2008), but to our knowledge, this is the first time that such a shortage has been associated with a major decline in a contiguous black bear population; notably the most severe decline that has been documented over a 1-year period. Hellgren et al. (2005) documented a similar decline, but their study focused on a small bear population ($N = 23$) existing in marginal habitat. In the absence of human development, natural food shortages have been found to have limited effects on bear populations. Under such conditions, recruitment is suppressed, which has little relative influence on bear population growth, whereas adult survival is unaffected (Beck, 1991; Kasbohm et al., 1996; Clark et al., 2005), the vital rate most important in driving bear population dynamics (Freedman et al., 2003; Beston, 2011). However, bears living near human development become much more susceptible to human-caused mortality (Hostetler et al., 2009; Baruch-Mordo et al., 2014; Obbard et al., 2014) as they shift their behaviors to forage on anthropogenic foods during natural food shortages. Indeed, the ultimate cause of the increase in

Fig. 6. Annual reported counts of 3 primary sources of human-caused mortality and all other sources combined (e.g., electrocution, natural, unknown) for male and female American black bears within the 841-km² study area in south-western Colorado from 2007 to 2014. Horizontal dashed line represents the 5-year average of total counts preceding a natural food shortage in 2012.

mortalities and population decline was the food shortage of 2012, which intensified proximate factors (e.g., human-bear interactions) that led to a much greater level of human-caused mortality within our study area compared with the previous 5 years. In particular, mortalities caused by vehicle collisions considerably increased. A similar pattern was recently observed in the vicinity of Aspen, Colorado, where sub-adult and adult survival declined ($\geq 26\%$) during poor natural forage years, largely as a consequence of bear-use of development and human-induced mortality (Baruch-Mordo et al., 2014).

The food shortage during the summer–fall period of 2012 primarily was the result of a late-spring frost event that severely reduced berry and nut production (Peterson, 2013; Rice et al., 2014). Late-spring frosts are known to cause mast crop failures (Neilson and Wullstein, 1980; Sharp and Sprague, 1967) and have been implicated in summer and fall food shortages in other bear populations (Beck, 1991; Obbard and Howe, 2008; Honda, 2013) indicating this phenomenon is not unique to our study system. Climate models predict, however, that these kinds of extreme weather events will likely become more common in the future (Karl et al., 2009), which may be problematic for bears; particularly as human development continues to expand across western landscapes. Lewis et al. (2014) used stochastic population simulation to evaluate the effects of increasing frequency of poor natural food years and various management-related removal scenarios on black bear populations. They found that a bear population could be sustained in scenarios with greater frequency of food failures if management removals were minimal, but would decline rapidly under scenarios where removals were high. However, the simulated demographic rates used by Lewis et al. (2014) to reflect poor food years corresponded to an asymptotic population growth rate of 0.77, a value far above the growth rate we estimated immediately following the food shortage in our study system ($\lambda = 0.43$). Although future food shortages may not be as severe as that which we observed in southwestern Colorado, we suggest that the effects of rare catastrophic events (e.g., population decline by $\geq 50\%$) be incorporated into long-term population assessments. This is especially important in the management of bears and

other k-selected large carnivores, which are demographically constrained in their ability to recover from population declines induced by episodes of high human-caused mortality.

Given our modeling approach, we could not explicitly separate individual contributions of in situ mortality and emigration to the observed population decline, but suspect that the decline was primarily caused by increased mortality. Emigration for female bears is rare, as they exhibit high natal site fidelity (Beeman and Pelton, 1976; Rogers, 1987b; Jones et al., 2015), a pattern supported by our telemetry data, as only 2 of 22 GPS-collared females emigrated from the study area in response to the food shortage of 2012. Alternatively, bears may temporarily shift or expand their home ranges or undertake long-range movements in response to food shortages (Pelton, 1989; Kasbohm et al., 1998; Hellgren et al., 2005; Baruch-Mordo et al., 2014). Such changes in space-use patterns may increase use of developed areas by bears, thereby increasing exposure to human-related sources of mortality (Noyce and Garshelis, 1997; Ryan et al., 2004; Ryan et al., 2007; Obbard et al., 2014). The high concentration of mortalities we observed in developed areas in 2012 indicates such a shift in space use likely occurred in response to the food shortage. Taken collectively, the relatively low number of collared females that emigrated, the increased level of human-caused mortalities reported during the food shortage (Fig. 6), and the concentration of those mortalities in developed areas (Fig. 4) further supports our conclusion that the population decline was primarily driven by human-caused mortality rather than emigration.

We also could not disentangle in situ reproduction and immigration processes with our SCR data set. However, we believe the effects of the food shortage on reproduction can be deduced from our estimates of population growth rate between 2013 and 2014 by making a similar assumption about immigration as for emigration in that high natal site fidelity of female bears also limits immigration. Reproductive failures commonly occur in bear populations immediately following mass food shortages due to poor body condition of parous females (Eiler et al., 1989; Bridges et al., 2011). Because black bear cubs (< 1 year old) typically were too small to be detected by our hair sampling methods (Laufenberg et al., 2016), evidence of contributions from in situ recruitment processes would lag (Clark et al., 2005) and not be detected until the following year. Based on the expectation of a 1-year lag in observing a recruitment failure in our data, the net effect would be a population growth rate slightly below 1.0 for the second year following a food shortage (assuming adult survival returned to pre-food shortage levels). Our growth rate estimate from 2013 to 2014 was 0.95 (SE = 0.14) which supports the conclusion that in situ reproduction was also affected by the food shortage.

In addition to detecting a major overall population decline following the food shortage, we detected temporal changes in spatial distribution of female bears across the study area. In particular, we found that fewer female bears occurred in or near developed areas relative to undeveloped areas after the food shortage compared with density patterns prior to the food shortage (Fig. 4). We surmise that the observed changes were primarily driven by the spatial distribution and intensity of human-caused mortalities associated with roads and urban areas in those years (Fig. 4). Our inference was supported by greater estimated importance of the DEVELOPMENT covariate, a variable with a strong negative relationship with density, in 2013 following the failure. We also found that densities of female bears declined in areas of marginal habitat (e.g., high-elevation alpine) far from human development, which we presume was due to some bears leaving those areas to access food in or near areas of human development. Despite some benefits for bears of anthropogenic foods in developed environments (e.g., increased reproduction, larger body size, reduced home range; Beckmann and Berger, 2003; Beckmann and Lackey, 2008) the costs of elevated human-caused mortality can result in human development-wildland interfaces that operate as ecological traps (Nielsen et al., 2004; Beckmann and Lackey, 2008; Hostetler et al., 2009; Baruch-Mordo et al., 2014). Given the sharp decline in bear abundance estimated for

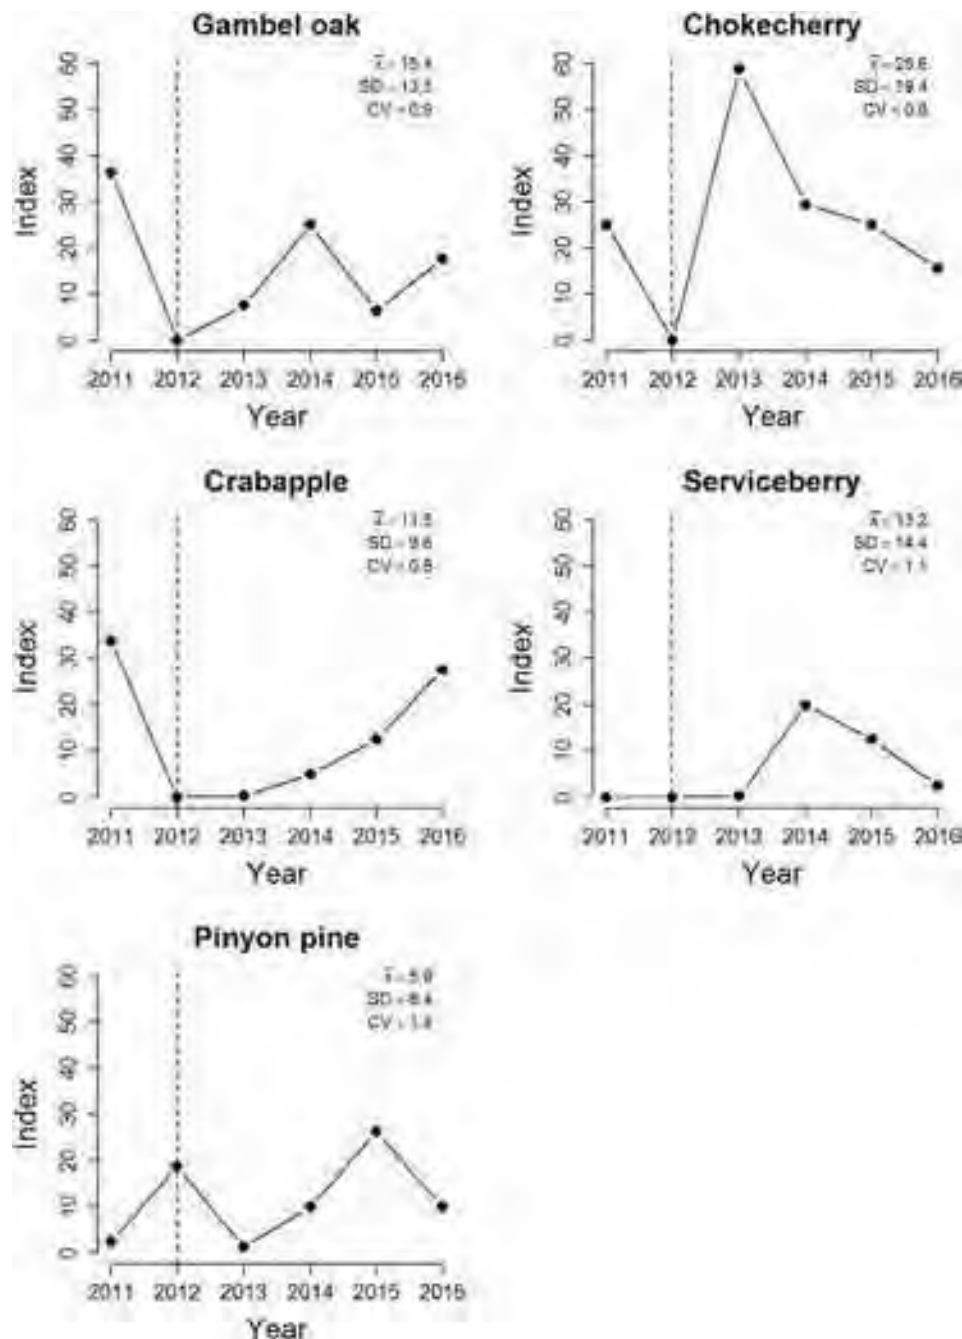

Fig. 7. Median abundance indices of 5 plants that provide hard and soft mast foods for American black bears in southwestern Colorado, USA from 2011 to 2016. The vertical dashed line indicates 2012, when there was a shortage of naturally occurring foods for black bears.

areas surrounding Durango, the overall increase in human-caused mortality following the food shortage, and the high density of those mortalities that occurred in and around development, our data would certainly support the notion that human development can serve as a population sink (Knight et al., 1988; Mattson et al., 1992; Ryan et al., 2007). This particularly is the case in poor natural food years when bears move greater distances in search for food, are attracted to town for access to anthropogenic foods, and suffer high mortality rates as a consequence (Baruch-Mordo et al., 2014). Furthermore, warmer temperatures and use of anthropogenic foods by bears have been linked to increased length of the active season which may result in even greater increases in human-caused mortality associated with developed areas thereby further exacerbating the compounding effects of predicted changes in human development and climate (Johnson et al., 2017).

Given expected increases in human development across the western U.S. (Leu et al., 2008), black bear population dynamics are likely to be increasingly influenced by non-harvest human-caused sources of mortality (e.g., vehicle collisions, lethal removals). Indeed, the annual number of non-harvest mortalities have been steadily increasing in Colorado over the past couple decades (Colorado Parks and Wildlife, 2015) as the state has seen corresponding increases in residential development, particularly in exurban and rural areas. If the frequency and severity of climate-related extreme weather events across the U.S. increases as predicted (Karl et al., 2009), the compounding effects of increasing human development and climate-induced natural food shortages may become an important determinant of long-term viability for a greater number of bear populations (Lewis et al., 2014). This shift has important implications for management agencies that typically rely

on harvest data to manage bear populations with limited information about bear population size or trend (Garshelis and Hristienko, 2006). The severe population decline detected in our study would have gone unnoticed from harvest data that are commonly collected and used to manage bears in Colorado, and was only detected due to monitoring efforts associated with an intense research project. Our results indicate management agencies may need to invest more resources into monitoring bear population trends, while accounting for non-harvest mortality rates in population models. For example, the novel integrated spatial capture-recapture approach we used could be optimized in terms of relative sampling effort for the both data types (i.e., capture-recapture and telemetry) to develop a cost-effective long-term monitoring solution.

Our results raise important questions about how management agencies can mitigate the compounding impacts of human development and natural food failures on bear populations in the future. In our system, vehicle collisions were a primary source of mortality, but effective mitigation strategies for this mortality source are unclear. In the southeastern United States, researchers have recommended the construction of highway underpasses (McCown et al., 2008; van Manen et al., 2012) but those systems differ in that bears are more continuously exposed to areas of high human density. In our system, bears are primarily drawn to development during periods of poor natural food availability. Therefore, a better strategy may be to reduce anthropogenic attractants and, thus, reduce the incentives for bears to forage within development (Baruch-Mordo et al., 2013; Johnson et al., 2018). As non-harvest human-caused mortality increases, management agencies may also need to reduce harvest and other lethal management actions to increase survival and ensure the long-term sustainability of bear populations.

Effects of Hunting on a Puma Population in Colorado

KENNETH A. LOGAN,¹ *Colorado Parks and Wildlife, 2300 S. Townsend Avenue, Montrose, CO 81401, USA*

JONATHAN P. RUNGE, *Colorado Parks and Wildlife, 317 W. Prospect Road, Fort Collins, CO 80526, USA*

ABSTRACT We investigated effects of regulated hunting on a puma (*Puma concolor*) population on the Uncompahgre Plateau (UPSA) in southwestern Colorado, USA. We examined the hypothesis that an annual harvest rate averaging 15% of the estimated number of independent individuals using the study area would result in a stable or increasing abundance of independent pumas. We predicted hunting mortality would be compensated by 1) a reduction in other causes of mortality, thus overall survival would stay the same or increase; 2) increased reproduction rates; or 3) increased recruitment of young animals. The study occurred over 10 years (2004–2014) and was designed with a reference period (years 1–5; i.e., RY1–RY5) without puma hunting and a treatment period (years 6–10; i.e., TY1–TY5) with hunting. We captured and marked pumas on the UPSA and monitored them year-round to examine their demographics, reproduction, and movements. We estimated abundance of independent animals using the UPSA each winter during the Colorado hunting season from reference year 2 (RY2) to treatment year 5 (TY5) using the Lincoln-Petersen method. In addition, we surveyed hunters to investigate how their behavior influenced harvest and the population. We captured and marked 110 and 116 unique pumas in the reference and treatment periods, respectively, during 440 total capture events. Those animals produced known-fate data for 75 adults, 75 subadults, and 118 cubs, which we used to estimate sex- and life stage-specific survival rates. In the reference period, independent pumas more than doubled in abundance and exhibited high survival. Natural mortality was the major cause of death to independent individuals, followed by other human causes (e.g., vehicle strikes, depredation control). In the treatment period, hunters killed 35 independent pumas and captured and released 30 others on the UPSA. Abundance of independent pumas using the UPSA declined 35% after 4 years of hunting with harvest rates averaging 15% annually. Harvest rates at the population scale, including marked independent pumas with home ranges exclusively on the UPSA, overlapping the UPSA, and on adjacent management units were higher, averaging 22% annually in the same 4 years leading to the population decline. Adult females comprised 21% of the total harvest. The top-ranked model explaining variation in adult survival (\hat{S}) indicated a period effect interacting with sex. Annual adult male survival was higher in the reference period ($\hat{S} = 0.96$, 95% CI = 0.75–0.99) than in the treatment period ($\hat{S} = 0.40$, 95% CI = 0.22–0.57). Annual adult female survival was 0.86 (95% CI = 0.72–0.94) in the reference period and 0.74 (95% CI = 0.63–0.82) in the treatment period. The top subadult model showed that female subadult survival was constant across the reference and treatment periods ($\hat{S} = 0.68$, 95% CI = 0.43–0.84), whereas survival of subadult males exhibited the same trend as that of adult males: higher in the reference period ($\hat{S} = 0.92$, 95% CI = 0.57–0.99) and lower in the treatment period ($\hat{S} = 0.43$, 95% CI = 0.25–0.60). Cub survival was best explained by fates of mothers when cubs were dependent ($\hat{S}_{\text{mother alive}} = 0.51$, 95% CI = 0.35–0.66; $\hat{S}_{\text{mother died}} = 0.14$, 95% CI = 0.03–0.34). The age distribution for independent pumas skewed younger in the treatment period. Adult males were most affected by harvest; their abundance declined by 59% after 3 hunting seasons and we did not detect any males >6 years old after 2 hunting seasons. Pumas born on the UPSA that survived to subadult stage exhibited both philopatry and dispersal. Local recruitment and immigration contributed to positive growth in the reference period, but recruitment did not compensate for the losses of adult males and partially compensated for losses of adult females in the treatment period. Average birth intervals were similar in the reference and treatment periods (reference period = 18.3 months, 95% CI = 15.5–21.1; treatment period = 19.4 months, 95% CI = 16.2–22.6), but litter sizes (reference period = 2.8, 95% CI = 2.4–3.1; treatment period = 2.4, 95% CI = 2.0–2.8) and parturition rates (reference period = 0.63, 95% CI = 0.49–0.75; treatment period = 0.48, 95% CI = 0.37–0.59) declined slightly in the treatment period. Successful hunters used dogs, selected primarily males, and harvested pumas in 1–2 days (median). We found that an annual harvest rate at the population scale averaging 22% of the independent pumas over 4 years and with >20% adult females in the total harvest greatly reduced abundance. At this scale, annual mortality rates of independent animals from hunting averaged 6.3 times greater than from all other human causes and 4.6 times greater than from all natural causes during the population decline. Hunting deaths were largely additive and reproduction and recruitment did not compensate for this mortality source. Hunters generally selected male pumas, resulting in a decline in their survival and abundance, and the age structure of the population. We recommend that regulated hunting in a

Efectos de la Cacería en una Población de Pumas en Colorado

RESUMEN Investigamos los efectos de la cacería regulada en la población de pumas (*Puma concolor*) de la Uncompahgre Plateau (UPSA) en el suroeste de Colorado, USA. Exploramos la hipótesis de que una cosecha anual con una tasa promedio del 15% del número estimado de pumas independientes que están usando el área de estudio resultaría en una abundancia estable o un incremento de pumas independientes. Nuestra predicción de que la mortalidad por cacería sería compensada por: 1) una reducción en otras causas de mortalidad, por lo tanto, la supervivencia se mantendría igual o incrementaría; 2) un incremento en la tasa reproductiva; o 3) un incremento en el reclutamiento de pumas jóvenes. Este estudio se llevó a cabo a lo largo de 10 años (2004–2014) y fue diseñado con un periodo de referencia (años 1 al 5; RY1–RY5) sin cacería de pumas y un periodo de tratamiento (años 6–10; i.e., TY1–TY5) con cacería de pumas. Capturamos y marcamos pumas en la UPSA y se llevó a cabo el monitoreo a lo largo de todo el año para examinar la demografía, reproducción y movimientos de los pumas. Estimamos la abundancia de pumas independientes que usaban la UPSA cada invierno durante la estación de cacería de pumas en Colorado usando el año 2 (RY2) como referencia al año de tratamiento 5 (TY5) usando el método de Lincoln-Petersen. Adicionalmente, llevamos a cabo prospecciones con cazadores para investigar como el comportamiento de los cazadores influía la cosecha y la población de pumas. Capturamos y marcamos un total de 110 y 116 pumas únicos dentro del periodos de referencia y de tratamiento, respectivamente, a lo largo de un total de 440 eventos de captura. Esos pumas produjeron datos de mortalidad con información conocida para 75 adultos, 75 sub-adultos y 118 cachorros, con los cuales se estimaron tasas de supervivencia específicas por sexo y etapas de vida. En el periodo de referencia la abundancia de pumas independientes se incrementó a más del doble y exhibieron una supervivencia alta. La mortalidad natural fue la mayor causa de muerte en pumas independientes, seguida de causas producidas por seres humanos (e.g. atropellamientos, control de depredadores). En el periodo de tratamiento, los cazadores mataron 35 pumas independientes, adicionalmente capturaron y dejaron en libertad a 30 pumas en la UPSA. La abundancia de pumas independientes se redujo en un 35% después de 4 años de cacería con tasas de aprovechamiento con un promedio anual de 15% en la UPSA. Las tasas de aprovechamiento a la escala de población incluyendo pumas independientes marcados con ámbitos hogareños exclusivos dentro de la UPSA, con sobreposición en la UPSA y en unidades adyacentes de manejo fueron mayores, en promedio 22% anualmente durante los mismos 4 años que llevaron a la población al declive. Las hembras adultas comprendieron 21% de la cosecha total. El mejor modelo que explicaba la variación en la supervivencia (\hat{S}) de los adultos indicaba un efecto del periodo interactuando con el sexo. La supervivencia anual de los machos fue más alta durante el periodo de referencia ($\hat{S} = 0.96$, 95% CI = 0.75–0.99) que durante el periodo de tratamiento ($\hat{S} = 0.40$, 95% CI = 0.22–0.57). La supervivencia anual de las hembras fue 0.86 (95% CI = 0.72–0.94) en el periodo de referencia y 0.74 (95% CI = 0.63–0.82) durante el tratamiento. El mejor modelo de supervivencia en hembras sub-adultas, mostro que la supervivencia fue constante a través de los periodos de referencia y tratamiento ($\hat{S} = 0.68$, 95% CI = 0.43–0.84), donde la supervivencia de los machos sub-adultos exhibió el mismo patrón de supervivencia de los machos adultos: más alta en el periodo de referencia ($\hat{S} = 0.92$, 95% CI = 0.57–0.99) y menor en el periodo de tratamiento ($\hat{S} = 0.43$, 95% CI = 0.25–0.60). La supervivencia de los cachorros se explica mejor por el destino de sus madres, cuando estos son dependientes ($\hat{S}_{\text{madres vivas}} = 0.51$, 95% CI = 0.35–0.66; $\hat{S}_{\text{madres muertas}} = 0.14$, 95% CI = 0.03–0.34). La distribución por edades de los pumas independientes estuvo sesgada a animales jóvenes durante el periodo de tratamiento. Los machos adultos fueron los más afectados por el aprovechamiento, su abundancia se redujo en un 59% después de 3 temporadas de cacería, y una ausencia de machos >6 años de edad después de 2 temporadas de cacería. Los pumas nacidos en la UPSA que sobrevivieron a la etapa sub-adulta exhibieron características filopátricas y de dispersión. El reclutamiento local y la inmigración contribuyeron al crecimiento positivo en el periodo de referencia. Sin embargo, el reclutamiento no compenso por la pérdida de machos adultos y parcialmente compenso por la pérdida de hembras durante el periodo de tratamiento. El intervalo promedio entre nacimientos fue similar entre los periodos de referencia y tratamiento (periodo de referencia = 18.3 meses, 95% CI = 15.5–21.1; periodo de tratamiento = 19.4 meses, 95% CI = 16.2–22.6), mientras que el tamaño de camada (periodos de referencia = 2.8, 95% CI = 2.4–3.1; periodo de tratamiento = 2.4, 95% CI = 2.0–2.8) y las tasas de parición (periodo de referencia = 0.63, 95% CI = 0.49–0.75; periodo de tratamiento = 0.48, 95% CI = 0.37–0.59) declinaron ligeramente durante el periodo de tratamiento. Cazadores exitosos de pumas usaron perros, seleccionaron fundamentalmente machos y cosecharon pumas en 1–2 días (mediana). Encontramos a la escala de población una tasa de aprovechamiento anual de 22% del número de pumas independientes en un periodo de 4 años y donde >20% de

hembras adultas en la cosecha total redujeron en cantidad la abundancia de pumas. A esta escala, las tasas anuales de mortalidad de los pumas independientes por cacería fueron en promedio 6.3 veces mayores que todas las otras causas producidas por seres humanos, y 4.6 veces mayores que todas las causas de mortalidad natural durante la reducción en la población. La mortalidad por cacería era aditiva y la reproducción y el reclutamiento no compensaron a la mortalidad por cacería. Encontramos que los cazadores de pumas seleccionaron pumas machos, resultando en una reducción de la supervivencia, abundancia de machos y la estructura de edades dentro de la población. Recomendamos que la cacería regulada con base en una estructura poblacional de fuente-sumidero puede ser utilizada para conservar a las poblaciones de pumas, proporcionando oportunidades para la cacería sustentable de pumas y redirigir el conflicto entre pumas y seres humanos.

Effets de la Chasse sur une Population de Puma au Colorado

RÉSUMÉ Nous avons examiné les effets d'une chasse régulée sur une population de puma (*Puma concolor*) dans le plateau de l'Uncompahgre (UPSA) dans le sud-ouest du Colorado. Nous avons examiné l'hypothèse qu'un taux annuel de récolte de 15% du nombre estimé de pumas indépendants utilisant l'aire d'étude maintiendrait l'abondance ou accroîtrait l'abondance de pumas. Nous avons prédit que la mortalité par la chasse serait compensée par: 1) une réduction des autres causes de mortalité, entraînant une augmentation ou stabilisation de la survie; 2) une augmentation du taux de reproduction; ou 3) une augmentation du recrutement de jeunes individus. L'étude a été conduite durant, et a été construite autour d'une période de référence (années 1 à 5) sans chasse aux pumas et une période de traitement (années 6 à 10) avec une chasse aux pumas. Nous avons capturé et marqué des pumas dans l'aire d'étude (UPSA) et les avons suivis toute l'année pour récolter des données concernant leur démographie, reproduction et mouvement. L'abondance de pumas indépendants a été estimée dans l'USPA à chaque hiver durant la saison de chasse aux pumas au Colorado de l'année de référence 2 (RY2) à l'année de traitement 5 (TY5) en utilisant la méthode de Lincoln-Petersen. De plus, nous avons sondé les chasseurs afin d'apprendre comment leur comportement influençait la récolte et la population de puma. Durant les périodes de référence et traitement, 110 et 116 pumas ont respectivement été capturés et marqués, durant 440 évènements de capture. Ces pumas ont produit des données dont le sort est connu pour 75 adultes, 75 subadultes, et 118 juvéniles qui ont été utilisés afin de modéliser le taux de survie de chaque sexe et groupe d'âge. Durant la période de référence, l'abondance des pumas indépendants a plus que doublé en abondance et montré un haut taux de survie. La mortalité naturelle était la cause principale de décès, suivie par les mortalités reliées à l'humain. Durant la période de traitement, les chasseurs ont tué 35 pumas indépendants et capturé puis relâché 30 pumas. L'abondance de pumas indépendants a décliné de 35% après 4 années de chasse avec des taux de récolte moyennant 15% dans l'UPSA. Les taux de récoltes à l'échelle de la population incluant des individus dont le domaine vital était à l'intérieur de l'USPA, chevauchant l'USPA, ou en périphérie de l'USPA étaient plus élevés et approchaient 22% durant les quatre années précédant le déclin de la population. Les femelles adultes représentaient 21% de la récolte total. Le meilleur modèle expliquant la variation dans la survie (\hat{S}) des adultes incluait un effet de la période en interaction avec le sexe. Le taux de survie des mâles adultes était plus élevé durant la période de référence ($\hat{S} = 0.96$, 95% CI = 0.75–0.99) que durant la période de traitement ($\hat{S} = 0.40$, 95% CI = 0.22–0.57). Le taux de survie des femelles adultes était de 0.86 (95% CI = 0.72–0.94) durant la période de référence et de 0.74 (95% CI = 0.63–0.82) durant la période de traitement. Le meilleur modèle du taux de survie des femelles subadultes a démontré que la survie était constante entre les deux périodes de traitement ($\hat{S} = 0.68$, 95% CI = 0.43–0.84) alors que le taux de survie des mâles subadultes a montré la même tendance que les mâles adultes: plus élevé durant la période de référence ($\hat{S} = 0.92$, 95% CI = 0.57–0.99) que durant la période de traitement ($\hat{S} = 0.43$, 95% CI = 0.25–0.60). Le taux de survie des petits était le mieux expliqué par le sort de la mère alors que les petits étaient dépendants ($\hat{S}_{\text{mère en vie}} = 0.51$, 95% CI = 0.35–0.66; $\hat{S}_{\text{mère en vie}} = 0.14$, 95% CI = 0.03–0.34). La structure des âges des pumas indépendants a décliné durant la période de traitement. Les mâles adultes étaient les plus affectés par la récolte, leur abondance a décliné de 59% après trois saisons de chasse et aucun individu de plus de 6 ans n'était présent après deux saisons de chasse. Les pumas nés dans l'UPSA qui ont survécu au stage subadulte ont exhibé de la philopatrie et de la dispersion. Le recrutement local et l'immigration ont contribué au taux de croissance durant la période de référence. Le recrutement n'a pas compensé pour la perte de mâles adultes et a compensé partiellement pour la perte de femelles adultes durant la période de traitement. L'intervalle moyen des naissances est demeuré similaire (période de référence = 18.3 mo., 95% CI = 15.5–21.1; période de traitement = 19.4 mo., 95% CI = 16.2–22.6), alors que la taille des portées (période de référence = 2.8, 95% CI = 2.4–3.1; période de traitement = 2.4, 95% CI = 2.0–2.8) et le taux de parturition (période de

référence = 0.63, 95% CI = 0.49–0.75; période de traitement = 0.48, 95% CI = 0.37–0.59) ont diminué légèrement durant la période de traitement. Les chasseurs de pumas qui ont eu du succès ont utilisé des chiens, ils sélectionnaient principalement les mâles et ont récolté des pumas à l'intérieur de 1–2 jours (médiane). Nous avons trouvé qu'un taux de récolte moyen avoisinant 22% du nombre estimé de pumas indépendants sur quatre ans et avec >20% de femelles adultes dans la récolte réduisait grandement l'abondance de puma. À cette échelle, le taux de mortalité annuel provenant de la chasse était en moyenne 6.3 fois plus grand que le taux provenant de tous les autres causes de mortalité humaine et 4.6 fois plus grand que le taux de mortalité de source naturelle durant la période de déclin de la population. La mortalité par la chasse était largement additive et la reproduction et le recrutement n'ont pas compensé pour cette source de mortalité. Nous avons trouvé que les chasseurs montraient une sélection pour les pumas mâles, entraînant alors une réduction de la survie et de l'abondance des mâles et impactant la structure des âges de la population. Nous recommandons qu'une chasse régulée dans une structure source-puit peut être utilisée afin d'aider la conservation des pumas, procurer des opportunités de chasse durable, et adresser les conflits pumas-humains.

INTRODUCTION

Large carnivores in North America are managed and conserved based on public interests and institutional policies and actions (Young and Goldman 1946, Kellert et al. 1996, Pavlik 2000, Gill 2010, Clark et al. 2014b). Species in this group include the jaguar (*Panthera onca*), wolf (*Canis lupus*), black bear (*Ursus americanus*), grizzly or brown bear (*U. arctos*), polar bear (*U. maritimus*), and puma (*Puma concolor*). These carnivores are killed by humans for a variety of reasons: to mitigate potentially dangerous encounters with people, to reduce predation on livestock and other wild animals deemed to have higher value, for subsistence or as commodities, for recreational gratification, and to obtain trophies for display (Amstrup et al. 1986, Pelton 2000, Clark et al. 2014b). Unrestricted hunting of carnivores and state-sanctioned predator control programs up to the mid-1900s caused range-wide population declines and regional

extirpations of the puma (Young and Goldman 1946, Cahalane 1964), jaguar (Brown and López González 2001), wolf (Young and Goldman 1944, Mech 1970, Brown 1984), black bear (Pelton 2000, Scheick and McCowan 2014), and grizzly bear (Mattson and Merrill 2002). As people recognized the rarity of these animals and society modernized, attitudes toward nature shifted from traditional domination and utilitarian views to more ecological, aesthetic, and compassionate ones that fostered tolerance and stewardship of large carnivores (Kellert and Berry 1987, Teel and Manfredo 2009, Gill 2010, Peek et al. 2012, Manfredo et al. 2018). These changes resulted in laws and policies to conserve sustainable populations of large carnivores while also managing them to satisfy other public benefits including human safety, protection of private property, and recreational hunting of the carnivores and their prey.

Large carnivores in the United States that are protected under the Endangered Species Act (ESA) have included the wolf,

grizzly bear, jaguar, eastern cougar (*P. concolor cougar*), and Florida panther (*P. concolor coryi*; Department of the Interior 1973). Recent genomic taxonomy designates all pumas in North America as *P. concolor cougar* (Culver et al. 2000); therefore, the eastern cougar was removed from the list in 2018 (U.S. Fish and Wildlife Service 2018). Despite its lack of genetic subspecies status, the Florida panther has retained its ESA listing and is the only known breeding puma population in the eastern United States. Conservation activities under the ESA were effective in increasing the abundance and distribution of the Florida panther (Lotz 2017), wolf (Musiani and Paquet 2004), and grizzly bear (Schwartz and Gunther 2006, Kendall et al. 2009) in portions of their range. As populations of these carnivores meet established recovery goals and criteria for removal from the ESA list, management authority is granted back to the states encompassing the distribution of the species (e.g., the wolf in Montana; Montana Fish, Wildlife and Parks 2018). Likewise, state legislatures enacted laws conserving other large carnivores that were deemed more viable, including the puma in western North America and the black bear, and identified these carnivores as harvestable species with game status and attendant restrictions on hunting. State wildlife management agencies were entrusted with enforcing the laws and developing management programs for these species at the behest of public beneficiaries and policy-makers (Pelton 2000, Anderson et al. 2010, Organ et al. 2012).

State management programs for carnivores enable wildlife managers to pursue a variety of objectives in the public interest, including conservation, hunting opportunity, human safety, reducing predation on wild ungulates, and mitigating damage to private property, including livestock. Moreover, big game hunting opportunities generate revenue from the sale of hunting licenses and taxes on hunting equipment, which help finance law enforcement, habitat improvements, monitoring, and research. Together, public involvement, associated revenue, and professional management are key components of a process known as The North American Model of Wildlife Conservation (Organ et al. 2012).

Pumas gained the legal status of game animal in all of the western and Pacific states of the contiguous United States and the Canadian provinces of British Columbia and Alberta from 1965–1973. The states of North Dakota and South Dakota followed in 1991 and 2003, respectively (Nowak 1976, Anderson et al. 2010). In California, the status of the puma was changed again to specially protected mammal in 1990, which prohibited recreational hunting (Updike 2005). In jurisdictions allowing hunting, state and provincial governments defined puma hunting seasons, and methods and amount of harvest. Restrictions on hunting apparently enabled populations to rebound from low numbers in the 1960s when, for example, 7 western states (CA, CO, ID, NM, OR, UT, and WA) each reported puma abundances in the hundreds (Cahalane 1964). By the early 2000s, those same states each reported puma abundances ranging from 2,000–6,000 (Becker et al. 2003, Whittaker 2005). As puma populations increased, however, harvest also increased and may have contributed to populations stabilizing or declining in some western states, warranting attention from wildlife managers (Dawn 2002, Lambert et al. 2006,

Nadeau 2008, Anderson et al. 2010, Montana Fish, Wildlife and Parks 2019).

The ecological role of pumas is integral to wildlife management and conservation. Pumas affect the abundances, distributions, and behaviors of ungulate prey through predation (Hornocker 1970, Logan and Sweanor 2001, Laundré 2010) and compete with other carnivores (Kunkel et al. 1999, Ruth and Murphy 2010, Ruth et al. 2019). Remains of puma-killed animals also provision food for scavenging vertebrates and invertebrates (Elbroch and Wittmer 2012, Barry et al. 2018). These attributes, along with the puma's characteristically large home ranges and long-distance dispersal movements, identify it as a potential focal species for conservation planning (Beier 2010).

Public attitudes concerning recreational hunting of pumas vary (Teel et al. 2002, Casey et al. 2005, Gigliotti 2005) and can restrict management options. Some public and legal challenges to hunting led to citizen ballot initiatives that prohibited hunting in California in 1990 and the use of dogs to hunt pumas in Oregon and Washington in 1994 and 1996, respectively (Mattson and Clark 2010, Negri and Quigley 2010). Consequently, in efforts to address multiple interests, managers develop management objectives to ensure that puma populations hunted for recreation are sustainable, and to reduce their abundance where needed to mitigate conflicts with people and predation on species of concern (Colorado Parks and Wildlife 2004). For managers to successfully attain such objectives, the effects of hunting on pumas must be understood.

Theoretically, puma populations are naturally limited by available food and regulated by density-dependent competition (Pierce et al. 2000, Logan and Sweanor 2001, Laundré et al. 2007, Logan 2019, Ruth et al. 2019). Hunting mortality may perturb these natural processes. A puma population segment (i.e., adults and subadults) that is below its ecological carrying capacity (i.e., the natural limit of a population set by resources in the environment; Fryxell et al. 2014) and growing can sustain a certain level of hunting without declining if that mortality is compensated (Williams et al. 2001). Compensation may result from reduced mortality rates from other factors (e.g., natural mortality), increased reproduction (e.g., larger litters, shorter birth intervals), or increased recruitment of young pumas born *in situ* or as immigrants. Any of these might occur if the removal of some animals through hunting improves conditions for surviving animals. If hunting mortality is compensatory, the population is expected to increase or remain stable. If these mechanisms do not adequately compensate for hunting mortality, however, then puma harvest produces additive mortality to the extent that the population stops growing or declines over time. When this happens, hunting mortality limits population growth.

Information regarding the effects of hunting on puma populations is sparse. Researchers in Nevada claimed a sustainable puma harvest up to 30% but did not provide any data (Ashman et al. 1983). Another source used to support up to a 21% sustainable puma harvest rate came with a caveat from the original authors that there were 3 interceding years with no harvest so the annual sustainable harvest rate was unknown (Ross and Jalkotzy 1992).

The first experimental removal of pumas occurred in Utah in 1987–1989 with a 1-time removal of 6 individuals (3 adults: 1 male and 2 female; 3 yearlings: 2 male and 1 female) in 1 winter (Feb–Mar), representing an estimated 27% of harvest-age (>1 yr old) animals in the population, which included 6 dependent kittens (Lindzey et al. 1992). One year after removal, the abundance of adult pumas was almost fully recovered, except for possibly 1 male. The harvestable population, however, was still 27% below the pre-removal number because of a deficit of animals in the population >1 year old. The researchers also observed 2 other adult puma deaths in the same year, which added to the total mortality. Thus, they concluded that a second year of similar removal could have further delayed population recovery.

Researchers studying pumas in New Mexico from 1985–1995 used the rate of population growth independent of hunting to estimate harvest rates that might result in sustainable populations (Logan and Sweanor 2001). The adult portions of 2 protected puma populations increased by average annual rates as high as 17–28% over 3 4-year periods after initial declines caused by culling. Logan and Sweanor (2001) found that population growth was apparently density dependent because average annual growth rates began to decline from 17% to 5% over 2 consecutive 4-year periods. The average annual observed rate of increase was 11%. The authors suggested that sustainable hunting mortality of the population should not exceed 11% of the adult pumas per year. Conversely, if the objective was population reduction, hunting mortality should exceed 11% of adults per year.

Consequently, when Colorado Parks and Wildlife (CPW) managers developed state-wide puma hunting management plans in 2004, they had to rely on sparse information and their professional judgment (CPW 2004). Managers assumed that to manage for a stable or increasing population, mortality rates of independent pumas (i.e., adults [usually >2 yr old] and subadults [immature animals independent from mothers, usually 1–2 yr old]) should be limited within the range of 8–15% of the expected abundance of independent animals. To reduce the population, managers assumed that mortality rates should be $\geq 16\%$ (Apker 2005). Prior to our research, none of these hunting management assumptions had been tested for biological validity. To address this need, we examined effects of hunting on a population in Colorado. Because of logistical and funding constraints, we were unable to replicate this large-scale study on more than 1 geographic area. Our study took place over 10 years (2004–2014) with 2 5-year periods: a reference period (years 1–5, hereafter RY1–RY5) and a treatment period (years 6–10, hereafter TY1–TY5). In the reference period, puma hunting was prohibited; this provided baseline estimates for population variables without hunting. The treatment period occurred on the same study area and included regulated hunting to provide information on effects of hunting on the population.

To best assist CPW managers, we posited that the upper mortality limit expected to result in a stable or increasing population was the most important variable to establish. Thus, our goal was to investigate harvest rates that maintained a stable or increasing abundance of independent pumas. Accordingly, we predicted hunting mortality would be compensated by 1) a

reduction in other causes of mortality, thus overall survival would stay the same or increase; 2) increased reproduction rates; or 3) increased recruitment of young pumas. Alternatively, we predicted that hunting mortality would be additive, and the population would decline. If mortality was additive, we expected to observe 1) no reduction in other causes of mortality, thus overall survival would decline; 2) no enhanced reproduction; and 3) no enhanced recruitment to fully compensate for hunting mortality. In addition, we investigated whether the behavior of hunters influenced harvest structure, and thus any emerging changes to puma population sex and age structure, by surveying hunters to gather information on their hunting methods and preferences.

STUDY AREA

The study area was the southern half of the Uncompahgre Plateau (in Mesa, Montrose, Ouray, and San Miguel counties of Colorado; Fig. 1), a montane highland oriented southeast to northwest and incised with canyons in the Colorado Plateaus Physiographic Province (Sinnock 1978). The Uncompahgre Plateau Study Area (hereafter UPSA) was 2,996 km² and was managed similarly to a Game Management Unit (GMU) except that puma hunting was manipulated for our research design. The UPSA would rank as the eighth largest by area of 185 GMUs in Colorado (range = 71–4,460 km², \bar{x} = 1,457 km²). The UPSA included about 477 km² of agricultural and residential development on the east and west flanks, and about 2,519 km² of wildland.

Vegetation on the UPSA transitioned from foothills covered in piñon-juniper (piñon pine [*Pinus edulis*] and juniper [*Juniperus* spp.]) woodlands starting at about 1,700 m in elevation to

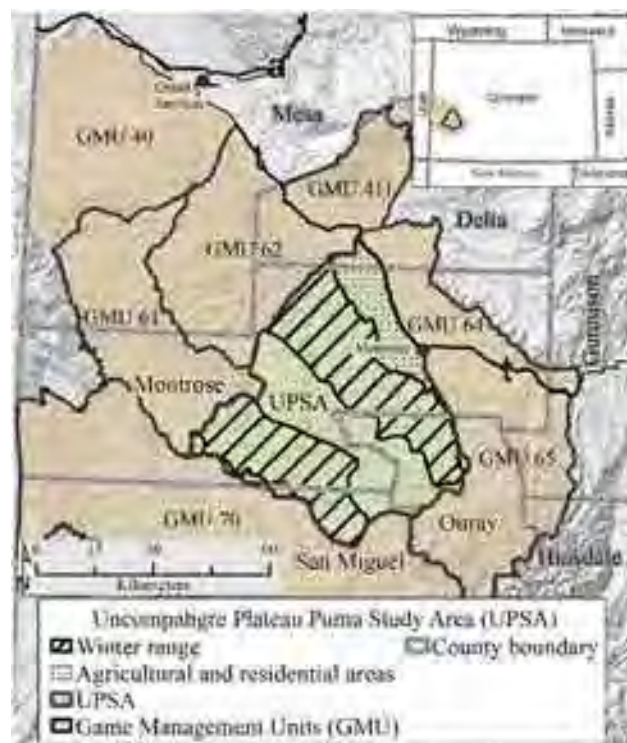

Figure 1. The Uncompahgre Plateau Study Area (UPSA) and surrounding Game Management Units (GMU) in Colorado, USA, 2004–2014.

woodlands dominated by Ponderosa pine (*Pinus ponderosa*) at mid-elevation to the spruce-fir (Engelmann spruce [*Picea engelmannii*], subalpine fir [*Abies lasiocarpa*], and Douglas-fir [*Pseudotsuga menziesii*]) and aspen (*Populus tremuloides*) forests at the highest elevations of about 3,000 m. Mid-elevation forests were interspersed with oak-serviceberry (Gambel oak [*Quercus gambelii*] and Saskatoon serviceberry [*Amelanchier alnifolia*]) shrublands. Expansive sagebrush-steppe (sagebrush [*Artemisia* spp.] and -grass) meadows and basins occupied mid-to-high-elevations, especially in the south-central portion of the area.

Weather was somewhat similar during the reference period years (2005–2009) and treatment period years (2010–2014), as recorded at Sanborn Park on the west side of the UPSA (108°13'00", 38°11'30", 2,417-m elevation) by the United States Department of Agriculture, Forest Service (Western Regional Climate Center, 2005–2014 climate summaries, <https://raws.dri.edu/wraws/coF.html>, accessed 2 Feb 2019). The reference period was characterized by an average annual precipitation of 35.5 cm (range = 29.0–41.3), average December temperature of -4.6°C (range = -24.4–13.3), and average July temperature of 19.8°C (range = 7.8–35.0). The treatment period was characterized by a slightly higher average annual precipitation of 45.8 cm (range = 31.5–51.8), and similar average December temperature (-3.4°C, range = -23.3–12.8) and average July temperature (19.4°C, range = 2.2–33.9).

The prey community available to puma on the UPSA was diverse, and included wild and domestic animals. Mule deer (*Odocoileus hemionus*) and elk (*Cervus elaphus*) were common on the Uncompahgre Plateau and surrounding areas. Adult pumas on the UPSA preyed primarily on mule deer and elk, and killed them in approximately equal proportions (Alldredge et al. 2008). In winter (Nov–Mar) the study area consisted of about 1,701 km² of lower elevation core winter range (980 km² east slope, 721 km² west slope) for pumas, mule deer, and elk that migrated there as snow accumulated at higher elevations. Cattle and domestic sheep grazed on high-elevation summer ranges and low-elevation pastures in winter. Cattle were rare prey for pumas, with 1 recorded killed during this study. Sheep were occasional prey for pumas, with 10 recorded incidents during this study, each involving 1–20 sheep. Mostly rural, year-round human occupation occurred along the eastern and western fringes of the area. Other animals kept by people included alpacas, llamas, goats, and pigs. There were 5 recorded incidents of puma predation on these animals during this study, with each incident involving 1–4 animals (CPW, Game Damage Program, unpublished data).

Potential competitors with pumas were coyotes (*Canis latrans*), black bears (*Ursus americanus*), and human hunters. Coyotes were subject to a year-round unlimited hunting season. Black bear hunting was regulated during a September to November season each year. Humans hunted mule deer and elk during annual fall big game seasons.

Prior to our research, pumas on the UPSA were subject to annual regulated hunting from mid-November through March. During the 5 previous years (1999–2003) an average of 12 pumas (range 8–17) were reported killed by hunters on the study area each year (CPW, unpublished data). Based on the

Figure 2. Number of adult and subadult female (F) and male (M) pumas reported killed by hunters during 1999–2003 on the Uncompahgre Plateau Study Area prior to our study, Colorado, USA.

records of the sex and age classes of the animals killed, 41% were classified as adult females; the rest were adult males and subadults of both sexes (Fig. 2). Two other puma deaths were reported on the UPSA during that time span; 1 adult male was shot by a landowner in 2002, and 1 subadult male was struck by a vehicle in 2003.

METHODS

Puma Research and Management in Colorado

We designed this research within the existing context of puma management in Colorado. In Colorado, puma GMUs are subsets of 19 much larger Data Analysis Units (DAUs). Each DAU has a median of 6 (range = 2–14) GMUs. Sizes of DAUs range from 4,048–21,054 km² (\bar{x} = 9,282 km²). The GMU and DAU boundaries are delineated primarily so hunters can easily recognize boundaries (e.g., roads, rivers) for administering hunting management. We assumed GMUs and DAUs were not discrete puma populations because we expected the animals to move across administrative boundaries given that home ranges of adults in North America vary in size from about 50–700 km² (Logan and Sweanor 2010) and habitat in Colorado is well connected (McRae et al. 2005). In addition, we expected dispersing subadults to move across GMU and DAU boundaries (Anderson et al. 1992, Sweanor et al. 2000).

Colorado Parks and Wildlife managers attempt to manipulate puma abundance with hunting at the DAU scale. Within each DAU, they apply assumptions and judgments on density, sex and age structure, population growth rates, and impacts of hunting and other causes of mortality. Each GMU within a DAU is allocated a harvest quota (i.e., harvest limit) to spatially distribute harvest to achieve 1 of 2 desired DAU-wide population states: 1) a stable or increasing population to provide hunting opportunity and species conservation, and 2) a declining or low-phase population with hunting used to reduce puma conflicts with livestock, big game ungulates, and human safety while also providing hunting opportunity. Management plans for DAUs identify mortality rates of independent pumas expected to achieve the desired population states (i.e., 8–15% for stable or increasing, $\geq 16\%$ for declining).

Puma hunting seasons began in mid-November and ended in March, at latest. Quotas were not sex-specific. Successful hunters were required to report their kills to CPW within 48 hours

of harvest and present carcasses for inspection within 5 days of harvest. Harvest within a GMU was updated daily, and hunters were required to call a free telephone number before each hunting day to check whether GMUs were closed because quotas had been reached. Puma hunting ended in each GMU when the quota was reached or the end of the hunting season, whichever came first.

Field Methods

Capture, marking, sampling, and monitoring.—Capturing, marking, and fitting individual pumas with telemetry collars and monitoring them was essential to a number of research objectives, including obtaining data on population abundance, sex and age structure, reproduction, survival, mortality causes, and movements in relation to study area boundaries and emigration. We handled all animals in accordance with approved CPW Animal Care and Use Committee (ACUC) capture and handling protocols (ACUC file #08-2004, ACUC protocol #03-2007) following the American Society of Mammalogists (Sikes and the Animal Care and Use Committee of the American Society of Mammalogists 2016). We marked captured pumas with a telemetry collar, ear-tag (Allflex USA, Dallas, TX, USA), and tattoo. An identification number tattooed in at least 1 pinna was permanent and could not be lost unless the pinna was detached.

We captured pumas using trained dogs, cage traps, and by hand (for small cubs). Pumas captured with dogs usually climbed trees to take refuge. We anaesthetized adults and subadults captured for the first time or requiring a change in telemetry collar with Telazol (tiletamine hydrochloride-zolazepam hydrochloride) dosed at 5 mg/kg estimated body mass. We delivered the drug into the caudal thigh or shoulder muscles via a Pneu-Dart® shot from a carbon dioxide-powered pistol (Pneu-Dart X-Caliber; Pneu-Dart, Williamsburg, PA, USA) or by a syringe at the end of an extendable pole. We deployed a 3-m by 3-m square nylon net beneath the puma to catch it in case it fell. We immediately restrained individuals that fell into the net with a catch pole. If the puma stayed in the tree, one of us climbed the tree, fixed a rope to 2 legs of the animal and lowered it to the ground with an attached climbing rope. Some pumas jumped from the tree after being struck by the dart. In those cases we followed its tracks until we found it sedated on the ground. To secure the animal, we covered its head, tethered its legs, and then monitored its vital signs. We considered normal signs to be pulse = 70–80 bpm, respiration = 20 bpm, a capillary refill time of ≤ 2 seconds, and rectal temperature = 38.3°C average (range = 35–40°C; Kreeger et al. 1999). We recorded the sex and dental characteristics of each puma we handled and measurements of each adult and subadult animal, including the length and width of plantar pads (mm measured with calipers), total length, tail length, chest girth, hind foot lengths (cm measured with a steel tape), and weight (kg measured with a spring scale). When a treed puma could not be safely immobilized and handled, we simply recorded the individual's sex, life stage, association with other individuals (e.g., mother, siblings), and location prior to leaving it.

Cage traps captured adults, subadults, and large cubs (Bauer et al. 2005, Sweanor et al. 2008). We lured animals to traps using road-killed or puma-killed ungulates. We set a cage trap

only if a target animal (i.e., an unmarked, required a collar change) scavenged on the lure. We continuously monitored a set cage trap from about 0.5–1 km distance by using very high frequency (VHF) beacons on the cage. This allowed us to respond to a captured puma in ≤ 30 minutes. We sedated them with Telazol injected into the caudal thigh or shoulder muscles with a syringe and restrained and monitored them as described previously.

We captured cubs at nurseries (i.e., nurslings) when mothers were away as determined by radio-telemetry. We captured cubs ≤ 10 weeks old using our hands covered with clean gloves or with a catch pole. We did not sedate these cubs with drugs, and instead restrained them inside new burlap bags. We removed cubs from nurseries at distances of about 20–100 m to reduce our disturbance of the nurseries. We marked each cub and recorded data on litter size. Afterwards, we immediately returned the cubs to the exact nurseries and vacated the area (Logan and Sweanor 2001).

We fitted captured adult and subadult pumas with either global positioning system (GPS; Lotek GPS 4400S) or VHF (Lotek LMRT-3; Lotek Wireless, Newmarket, Ontario, Canada) collars, each weighing about 400 g and 300 g, respectively. Budget constraints limited the number of GPS collars available annually; therefore, we fitted those collars primarily to adult pumas of both sexes. We fitted other adults and subadults with the VHF collars.

We attempted to collar all cubs in each observed litter of nurslings with a small VHF transmitter (model 080; Telonics, Mesa, AZ USA) mounted on an expandable collar (total weight 62 g) when cubs weighed 1.3–10 kg. The collars could expand to 54 cm circumference to accommodate growth to the adult stage. We fitted cubs weighing ≥ 7 kg with a larger expandable collar weighing 90 g (model 210; Telonics) that also could expand to 54 cm circumference. We fitted cubs approaching the age of independence (11–14 months old) with Lotek LMRT-3 VHF collars each with a leather expansion link that added 10–14 cm to the collar circumference to accommodate an adult neck size.

We initially estimated the ages of adult pumas by the gum-line recession method (Laundré et al. 2000) and later with dental characteristics of known-age animals (i.e., observed from cubs to older ages) from this study. We recognize these aging methods are not exact for pumas with unknown histories. We found them useful, however, to place individuals into 2-year age increments to examine age structures and to back-age certain adults into previous winter counts. We estimated ages of subadults and cubs initially based on dental and physical characteristics of known-age pumas from New Mexico (K. A. Logan, Colorado Parks and Wildlife, unpublished data) and later from known-age animals in this study. We estimated the ages of nurslings from birth dates indicated by GPS and VHF location data of collared mothers.

We focused our capture efforts of adults and subadults in winter to gather data on harvest-age animals in association with the Colorado puma hunting season. During the reference period when no hunting was allowed, our capture team operated from early snow accumulation in November until April when high ambient temperatures and black bear emergence from hibernation affected the dogs' effectiveness. During the treatment

period, we began our dog-assisted capture operations after the UPSA puma-hunting quota was reached (Dec–Jan) so as to avoid interfering with hunters' activities or harvest preferences. Although this could have resulted in a shorter dog-assisted capture period, it was mitigated by deploying 2 capture teams. Houndsmen in our capture teams were not allowed to hunt pumas for sport on the UPSA during the treatment period.

The UPSA was accessible by roads and trails, enabling us to canvass the study area repeatedly each winter, and thereby facilitated our detection and capture of pumas. We searched less-accessible areas by hiking canyon rims and bottoms to detect puma tracks while allowing dogs to freely search for the animal's scent. Our objective was to apply intensive, uniform searching effort and to directly monitor via radio-telemetry a large majority of independent pumas that used the UPSA each winter. Thus, we prioritized our efforts to detecting and capturing non-collared independent animals. When we followed fresh tracks that led us to <1 km (usually <0.5 km) from GPS- and VHF-collared individuals based on strengthening radio-signals, we re-directed our efforts away from those animals and toward finding non-collared ones.

We monitored radio-collared pumas year-round. We programmed GPS collars to fix locations 4 times per day (0600, 1200, 1900, 2400) during RY1–TY2, then 2 times per day (1200, 2400) during TY3–TY5 to extend battery life. We attempted to locate all collared pumas once per week from fixed-wing aircraft as weather and scheduling conditions allowed, and opportunistically from the ground (Logan and Sweanor 2001). We checked the live or dead signal status from collared pumas during aerial and ground telemetry. The VHF and GPS collars had mortality modes set to alert researchers when animals were immobile for 3 hours and 24 hours, respectively, so that we could examine dead pumas. We downloaded GPS collars remotely roughly once per month to retrieve location data. Emigration from the study area was revealed by movements of radio-collared animals or hunter returns of ear-tags from pumas killed outside of the study area. We investigated female pumas for evidence of reproduction whenever they exhibited constrained movements over a 1–4-week period with GPS and VHF location clusters of <300-m radius or recurring movements to farther distances that returned to focal locations (Logan and Sweanor 2001).

Hunting manipulation.—In the 5-year reference period, puma hunting was prohibited on the UPSA. In addition, any radio-collared or ear-tagged pumas that ranged off the UPSA onto GMUs 61 and 62 north of the UPSA were protected from hunting (Fig. 1). Otherwise, animals that were involved in depredation on livestock and public safety events on the UPSA and elsewhere could be killed following established CPW management policies.

In the 5-year treatment period, pumas on the UPSA were subjected to regulated hunting. The hunting season began in mid-November and ended the date that the last puma on the quota was killed each winter. The initial harvest quota was set at 8 pumas, which represented a 15% target harvest of the estimated number of 53 independent animals using the UPSA in TY1. We modeled this estimate from count data in winter RY4. After we detected a linear decline in winter counts of

independent pumas during TY1–TY3, we used a simple linear regression model to project the expected count for independent animals for TY4. The model projected 44 pumas, so we adjusted the harvest quota down to 5, an expected 11% target harvest in TY4, to examine the effect of a reduced harvest on abundance. We also applied the quota of 5 pumas in TY5 (Table S1, available online in Supporting Information).

During our 10-year study, puma hunting quotas on the GMUs bordering the UPSA did not vary annually, except in GMU 65. There annual quotas were 5 in RY1–RY4, 4 in RY5 and TY1, 5 in TY2 and TY3, and 6 in TY4 and TY5. All GMUs bordering the UPSA were in 2 DAUs of which 1 (including GMUs 61, 62, 64, and 65) had a management objective for a stable puma population and 1 (with GMU 70) had a management objective for a stable or increasing population (Fig. 1).

Hunter information.—Puma hunters on the UPSA were required to adhere to the same regulations as others in Colorado. Consistent with Colorado's puma hunting management, the number of hunters on the study area each winter was potentially unlimited because the actual harvest was limited by the quota. Puma hunters on the UPSA, however, were mandated to obtain a special hunting permit. Each hunter could obtain the free permit from the CPW Service Center in Montrose, Colorado. Each permit allowed the hunter to hunt in the UPSA for 14 days from the issue date. Unsuccessful hunters that wanted to continue hunting past the permit expiration date could get serial 14-day permits until they harvested a puma, stopped hunting, or until the end of the season. Each hunter also received a voluntary survey with their hunting permit and a stamped return envelope. We asked hunters to complete the survey as soon as possible for each period associated with the permit. Responsive hunters either mailed or handed in their surveys. If hunters did not respond to our first request, we tried to contact them a second time by telephone or in person, and asked them to complete and return the survey.

The permit system and survey responses provided data that included 1) permit holders that actually hunted on the UPSA; 2) number of days each hunted on the UPSA; 3) the sex of puma (we provided hunters with male and female track measurements) that made the first set of tracks <1 day old that a hunter encountered on the UPSA (representing the first theoretically catchable independent puma); 4) the sex and life stage of a puma harvested by the hunter on the UPSA; 5) counts and sexes of independent pumas that were captured and released by hunters on the UPSA; 6) if marks on the animal (i.e., collar, ear-tags) influenced a hunter's decision to harvest it; 7) if the hunter used dogs; and 8) self-identification as a selective or non-selective hunter. On this last point, we provided definitions. A selective hunter is one that purposely is hunting for a specific type of legal puma, such as a male, large male, or large female. The selective hunter attempts to distinguish between male and female tracks, and large and small males or females, and thus is deciding not to kill certain pumas. A non-selective hunter is one that intends to harvest whatever legal puma is first encountered or caught, with no preference for sex or size.

Our research personnel visually examined each puma harvested on the UPSA and officially marked it with a metal, numbered tag to indicate legal possession by the hunter, consistent with Colorado

hunting regulations. At the time of carcass check-in, hunters also completed a CPW mandatory harvest form, which included the puma's sex, age estimate, date of kill, and kill-site location.

Analysis

Abundance and growth rates.—The parameter of interest to wildlife managers was the abundance of independent pumas (i.e., adults and subadults) each winter coinciding with the hunting season in Colorado. Initially, we obtained an index of abundance of independent pumas that used the UPSA based on counts of animals we detected from November through March (i.e., winter counts) from RY4–TY3 (Table S1). We used this information for setting the hunting quotas in the treatment period. Winter puma counts consisted of the sum total of all individuals, including known marked, non-marked we captured but could not safely handle, and non-marked harvested on the UPSA. In addition, our counts included other individuals of unknown identity detected by their tracks as recorded by our capture teams on the study area. We concluded that individuals were unique if their track characteristics fit these criteria: 1) did not match known movements and locations of radio-collared pumas, 2) exhibited measurements that did not match those of individuals we subsequently captured, and 3) different counts of cub tracks with mother's tracks (e.g., mother's tracks associated with tracks indicating 1, 2, or 3 cubs would differentiate mothers). We used hind-foot plantar pad inside width measurements to distinguish sex (≥ 52 mm classified as male, ≤ 50 mm classified as female [measured with a steel ruler]).

After we compiled all our data on winter capture efforts, observed mortalities, and fates of pumas with non-functional collars, we used the Chapman method for the Lincoln–Petersen (LP) estimate (Petersen 1896, Lincoln 1930, Pollock et al. 1990) to estimate the number of independent pumas (i.e., \hat{N}_c) that used the UPSA from November through March each winter before any individuals were removed from the population from RY2–TY5:

$$\hat{N}_c = [(n_1 + 1)(n_2 + 1)/(m_2 + 1)] - 1 \quad (\text{Pollock et al. 1990:equation 2.2}).$$

This approach also provided estimates of variance:

$$\text{var } \hat{N}_c = (n_1 + 1)(n_2 + 1)(n_1 - m_2)(n_2 - m_2)/(m_2 + 1)^2 \times (m_2 + 2) \quad (\text{Pollock et al. 1990:equation 2.3})$$

and precision with 95% confidence intervals:

$$\hat{N}_c \pm 1.96 (\text{var } \hat{N}_c)^{0.5} \quad (\text{Pollock et al. 1990:11}).$$

We defined the LP parameters as n_1 = the number of marked independent pumas we expected to be using the UPSA at the start of each November, n_2 = the total number of independent pumas detected during the hunting and capture season, and m_2 = the number of the n_2 sample that was previously marked. We treated each capture and hunting season (Nov–Mar) as a single sampling period. This extended capture effort potentially minimized bias from capture heterogeneity by allowing sufficient time for us to search the entire study area, to use data on

puma captures both from our study team and hunters, and to detect individuals with home ranges that overlapped the border of the UPSA. Detections consisted of marked independent pumas recaptured by hunters, previously marked animals we recaptured during our winter capture operations, and radio-collared individuals we detected by following tracks toward radio-signals during our ground-capture operations. We counted radio-collared adults in the n_1 data with home ranges that overlapped the UPSA and adjacent areas as detected in the m_2 data if they were harvested on a portion of their home range off the UPSA. We counted adult pumas with failed radio-collars that had previously established home ranges on the UPSA in n_1 data in winters they were not detected if they were subsequently either recaptured or harvested (i.e., their fates were known) on the UPSA in subsequent winters. If any of these individuals had temporarily emigrated from the UPSA when they went undetected in any year, then the actual number of independent animals using the UPSA would be somewhat lower. In addition, we back-aged pumas with estimated ages ≥ 3 years old that we caught for the first time and assumed they were present on the UPSA the previous winter(s) beginning when they were ≥ 2 years old (e.g., a puma aged 3.5 years old in TY2 would be counted as a 2.5-year-old in TY1; Logan and Sweanor 2001); we counted those individuals in the n_2 data. If any of these individuals were actually absent in any of those years, again, the actual number of independent animals using the UPSA would be lower. We used the change in the LP \hat{N}_c estimates and the 95% confidence intervals as a gauge of changes in the population of independent pumas that used the UPSA during the reference and treatment periods. We recognize that this estimate of abundance assumes the population is closed, which this population is not. Therefore, the abundance estimates are biased (Seber 1982, Kendall 1999). However, this method is an improvement on the use of simple counts that are more susceptible to biases due to annual changes in detection probability and prone to errors of underestimation. We were unable to use a robust design capture-recapture model (Schwarz and Stobo 1997) because the sampling intervals were inadequate for that method. We attempted to use the Jolly-Seber approach to estimation of abundance (Jolly 1965, Seber 1965) in Program MARK (White and Burnham 1999), but models would not converge on a solution for the maximum likelihood. Other approaches to estimation of density rather than abundance (e.g., Efford 2004, Ivan et al. 2013) also assume closed populations and thus would invoke similar biases to our method.

We estimated the finite rate of change in abundance (λ) and its 95% confidence interval each year during the reference and treatment periods, RY2–TY5, to interpret changes in abundance without and with the hunting treatment (Fryxell et al. 2014). To calculate λ , we drew 10,000 samples using R statistical software (version 3.1.1; R Core Team 2018) for each year from a normal distribution using that year's LP \hat{N}_c estimate and its standard error. We calculated λ for each set of 10,000 samples by dividing the resulting estimate 1 year forward by the current year. The estimated λ was the median of this sample and the 2.5th and 97.5th percentile values defined the bounds of the 95% confidence interval.

Sex and age structure.—We quantified the sex and age structure of independent pumas on the UPSA each winter RY1–TY5 based on the animals that were captured and the LP estimates. We also used counts of cubs we captured and counts of non-captured cubs we detected from tracks associated with mothers. We graphed the sex and age structure annually for independent pumas that we physically examined (i.e., captured and handled or harvested) by sorting individuals into 2-year age increments (i.e., 1–2, >2–3 yr, and so on). The sex and age structures during the reference period (i.e., RY1–RY5) and up to the start of TY1 represented the population protected from hunting but subject to other causes of mortality and just before any pumas were removed in TY1. The subsequent age structures for the remainder of the treatment period (i.e., TY2–TY5) represented when hunting and other mortality factors affected the independent pumas.

Mortality.—We estimated cause-specific mortality rates of independent pumas at 2 spatial scales. The smaller, local scale included the number of independent pumas estimated to use the UPSA each winter, consistent with the way managers might conceive of applying harvest limits (i.e., quotas) to GMUs. The larger scale included the UPSA and 4 GMUs bordering the UPSA where marked pumas ranged (i.e., GMUs 61, 62, 65, 70; total area = 11,614 km²; none were on GMU 64). We examined fates of independent animals at this larger scale for 2 reasons: First, managers considered puma population segments at a DAU scale (i.e., population scale) for setting broad population state objectives. Second, we recognized that the local UPSA population was open and could be affected by fates of pumas ranging on the UPSA and adjacent GMUs.

The smaller scale represented mortality rates on the estimated number of independent pumas that used the UPSA each hunting season. We examined these mortality rates by using 2 metrics. The first metric represented the proportion of the expected number of independent animals using a GMU that died within the boundaries of the GMU to denote how managers may view mortality rates in units on which they limit the harvest and that are small relative to the population. We used simple quotients with the numerator as the number of independent pumas observed to have died within the UPSA boundaries each hunting season and the denominator being the LP \hat{N}_c estimated number of independent pumas using the UPSA each hunting season. These estimates were biased because the use of LP estimates in an open population can itself be biased, specifically in systems with non-random movement in and out of the study area (Seber 1982, Kendall 1999). Furthermore, the numerator only included animals that died within the UPSA boundaries, but the denominator included animals ranging on and off the UPSA; thus, the estimate was biased low. In the second metric, we accounted for the radio-collared pumas with home ranges overlapping the UPSA that were counted in the denominator and died on adjacent GMUs because their deaths affected future abundance estimates on the UPSA (i.e., independent pumas that died within UPSA plus independent pumas with overlapping home ranges that died on adjacent GMUs divided by the LP \hat{N}_c estimate of independent pumas using the UPSA). This metric could partially mitigate the biases in the first estimate but could not account for any non-marked

pumas estimated in the denominator that might have had home ranges overlapping the UPSA and died on adjacent GMUs.

At the population scale, we used all the marked independent pumas with known fates that ranged on the UPSA and on the 4 GMUs bordering the UPSA where marked animals were reported to have died to calculate annual rates of agent-specific mortality. We used simple quotients with the numerator being the number of marked individuals that died each biological year (i.e., Nov–Oct) and the denominator being the number of marked independent pumas alive at the beginning of each biological year. Likewise, we calculated rates at which marked pumas emigrated beyond the boundaries of the GMUs bordering the UPSA and considered those to be extra-population-scale movements. We calculated 95% simultaneous confidence intervals for the resulting multinomial proportions (Goodman 1965, May and Johnson 1997) of cause-specific mortality and movement.

For cubs, we counted mortalities and categorized them by proximate cause of death. We report numbers and percentages for each mortality type for the reference and treatment periods. We estimated the proportions of litters subject to infanticide in the reference and treatment periods by calculating the binomial proportions and Clopper-Pearson exact 95% confidence intervals by using the PROC FREQ procedure in SAS (version 9.3; SAS Institute, Cary, NC, USA).

Philopatry, dispersal, and emigration.—We defined pumas born on the study area as philopatric if any of their adult stage locations occurred within the 100% minimum convex polygon (MCP) of their mother's cumulative locations (Minimum Bounding Geometry tool, Convex Hull option, ArcGIS version 10.2; Esri, Redlands, CA, USA). We considered individuals born on the study area to have dispersed if none of their adult locations occurred within their mother's MCP. We measured dispersal distances in kilometers using the planar measuring tool in Arcmap 10.2 (Esri) from first captures at nurseries, with mothers or siblings, or as independent pumas to dispersal end points of last radio-telemetry locations or their mortality sites (e.g., harvest, vehicle strike, depredation control). We estimated age at independence (i.e., at the first observed date of separation from mothers without returning) and dispersal of previously radio-collared cubs (i.e., at date of first observed location outside of its mother's MCP without returning), and reported medians, averages, and 95% confidence intervals. We considered pumas that moved completely outside the boundaries of the UPSA to be emigrants. Those included some young independent animals that we captured and marked on the UPSA that could not be connected with known mothers but subsequently exited the UPSA. We estimated a minimum frequency of emigration of offspring from the UPSA by using the known-fate data on the radio-collared cubs we used in the survival analysis (below). Notably, these emigration rates were expected to be higher than the extra-population-scale emigration rates we estimated when analyzing puma mortality because of the shorter movement distance needed for individuals to exit the UPSA.

Survival.—We investigated puma survival in the reference and treatment periods to assess any effects of hunting. We defined the biological year for adult pumas as the period from November

(the month that hunting seasons began) through the next October to encompass complete hunting seasons. We estimated survival rates of subadults and cubs for 12-month periods representing those life stages. We used the known-fate data type and logit link function in Program MARK (White and Burnham 1999) to model survival rates with a candidate set of models that might explain variation in survival (below).

We defined adult pumas as >2 years old, unless we had evidence that they bred at an earlier age. In western North America, average ages of first breeding for samples of known-age females ranged from 23–28 months old and averaged 26.1 months (Utah, $n=6$, Lindzey et al. 1994; New Mexico, $n=12$, Logan and Sweanor 2001; Alberta, $n=6$, Ross and Jalkotzy 1992; Montana, $n=14$, Robinson and DeSimone 2011). That average value was close to the estimated average age of 29 months of first conception for a sample of 14 females in this study (see reproduction results). Furthermore, because our capture efforts for independent pumas were focused during November to April, the youngest animals in the adult stage in November generally could have been 26–32 months old, assuming they were born within the monthly distribution of births in our study. We did not have data on first reproduction for males in our study; however, males in New Mexico were estimated to reach sexual maturity at about 2 years old (Logan and Sweanor 2001).

We examined adult survival from data on radio-collared pumas. We converted radio-location records for each adult to monthly encounter histories. We used Program MARK to estimate monthly survival rates while allowing staggered entry based on when we collared individuals and censoring of individuals if we lost contact with them (Pollock et al. 1989). We used data from RY2–TY5. We did not use data from RY1 because we had collared only 7 adult pumas (3 males and 4 females). Encounter histories of individual adults started on the day of capture or the beginning of RY2 (i.e., 1 Nov 2005) for surviving pumas that we captured previous to that date. We censored individuals if we did not receive their radio-telemetry signal after the month of their last location. Individuals re-entered the data set if we recaptured them and fit them with a new collar. We used known death dates for individuals killed and reported by hunters, those killed for depredation control, and for some vehicle strikes. For individuals that died of other causes, we assigned death dates to those with GPS collars based on the first day that GPS locations indicated that they were immobile. For VHF-collared pumas, we estimated dates as the mid-point of the span of days in which we estimated the animal to have died based on detection of radio-collar mortality signals and carcass decomposition. We categorized causes of death as human causes (e.g., hunting, depredation control, vehicle strike, illegally killed), known natural causes (e.g., intraspecific killing), or unknown natural causes (e.g., presumed disease-related).

Subadult pumas are independent of their mothers and usually do not participate in breeding behavior (Logan and Sweanor 2001). We estimated subadult survival for all known radio-collared, ear-tagged, and tattooed pumas with known fates. Individuals entered the subadult stage under 2 conditions: 1) after they were known to be independent from their mother based on radio-telemetry, or 2) at 13 months if their date of

independence was not known. We used 24 months for the upper end of the range for subadults and 13 months as the lower end. Thirteen months is the median age ($\bar{x}=13.7$ months) for a sample of 15 pumas at known age of independence in this study (see results). Because we did not know exactly when all of the pumas in this life stage became independent, some of them may have been dependent cubs for ≥ 13 months. Encounter histories started when marked pumas entered the life stage and on the first day of capture for subadults caught and marked for the first time. We converted individual radio-telemetry records to monthly encounter histories. We assigned death dates as for adults.

We estimated cub survival for radio-collared pumas between 1–12 months old. Because the youngest cubs we radio-collared were 25 days old, we could not estimate mortality and survival rates for younger animals. The large majority (i.e., 85 of 118) of cubs in this data set were initially radio-collared as 1–2-month-old nurslings. We entered older cubs we collared in the analysis because we converted individual radio-telemetry records to monthly survival histories based on age. This simply allowed us to increase the sample sizes of cubs we monitored in the older months. Encounter histories for the cubs started on the first day they were collared. We assigned a cause of death to each cub and recorded known dates of occurrence. If dates of death were not observed, we used the mid-point of the span of days in which the puma was estimated to have died based on the radio-telemetry data and state of carcass decomposition.

Covariate selection, model selection, and inferences.—Examining survival rates of adults, subadults, and cubs in the reference and treatment periods allowed us to assess changes in survival that might be associated with hunting. A period (i.e., reference vs. treatment) effect would support an inference that hunting mortality was an important factor explaining the variation in puma survival. However, if models lacking the period result received the most support, this would indicate that survival was influenced mainly by other factor(s) or that statistical power was insufficient to detect a treatment outcome. Thus, we developed models with sets of covariates that we hypothesized might affect survival of adult, subadult, and cub pumas of either sex. Because selection of male pumas by hunters was evident, we also modeled adult and subadult survival by varying male survival by period while keeping female survival constant. We used year as a covariate for adults and month for subadults in time-varying models. Cub survival covariates also included period and whether a cub's mother lived or died during the stage of dependency. We modeled survival for all 3 life stages including constant, additive, and interactive combinations of some covariates. Reliable estimates of mule deer and elk abundances for the UPSA did not exist; thus, we could not accurately estimate the effect of a prey covariate.

We evaluated the importance of candidate models in an information-theoretic approach (Burnham and Anderson 1998). For adults and subadults, we used Akaike's Information Criterion adjusted for small sample sizes (AIC_c) to rank the models. We considered models with the lowest AIC_c scores, high AIC_c weights, and models with $\Delta AIC_c < 2$ as having the most support. We report survival estimates for the top model and other supported models. For adults, we used the monthly

survival rates generated in MARK and converted them to annual rates (i.e., S_{monthly}^{12}) with 95% confidence intervals. We used the delta method (Dorfman 1938) to calculate confidence intervals for annual survival rates. Likewise, we used monthly survival rates in MARK for subadults and converted them to life stage survival rates with 95% confidence intervals.

For cub survival, the assumption that each radio-collared individual was an independent random sample (i.e., distribution of mortalities among litters is random) may be violated because we often collared 2–3 cubs per litter, and the fates of siblings might be linked. For example, more than 1 cub in a litter may die from the same proximate cause (e.g., infanticide) or a cub's enhanced survival may be linked to death of siblings (i.e., resulting from greater individual maternal care). Violation of the independence assumption can result in unbiased survival point estimates, but sample variances are expected to be underestimated and the data are over dispersed (Bishop et al. 2008). Therefore, we examined validity of the independence assumption in the cub data by estimating an over dispersion parameter \hat{c} by following the method of Cooch and White (2015). We used the Tests option in Program MARK to run 1,000 bootstrap simulations on our cub data set in the most parameterized survival model we could use. We then estimated \hat{c} by dividing the observed \hat{c} in the original model estimate by the mean simulated \hat{c} . We considered $1.0 < \hat{c} \leq 1.2$ as weak evidence of over dispersion as suggested by Bishop et al. (2008) and Ruth et al. (2011). If the results indicated non-independence in the cub fates, we used the Adjustments option for \hat{c} in MARK and entered in the estimated \hat{c} to adjust for the quasi-likelihood estimate (QAIC_c). We considered the models with the lowest QAIC_c scores, high QAIC_c weights, and $\Delta\text{QAIC}_c < 2$ as having the most support. Survival parameters for cubs were monthly estimates generated in MARK that we converted to life stage survival rates with 95% confidence intervals.

Reproduction.—Females with GPS and VHF collars provided data on parturition (date), gestation (days), litter size (number), sex of cubs observed in nurseries, birth intervals (months), and age at first breeding (months). We verified reproduction by direct observations of cubs in nurseries and in association with adult females during capture events. We estimated ages for a sample of females when they produced their first litters that we observed. We assigned a non-productive status to females with nipples that were tiny and pink or white in color indicating no previous suckling. We reported mean age at first breeding, range, and 95% confidence intervals. We estimated gestation lengths for litters from the first and last days we detected females in association with adult males by GPS- and VHF-telemetry and to the estimated dates of births and reported minimum and maximum, medians, and means with 95% confidence intervals.

We estimated parturition rate, defined as the proportion of adult females giving birth each year, from RY2 through TY5 when ≥ 12 adult females occurred in annual samples ($n = 4$ for RY1). We recorded whether or not individual adult females produced litters each year during the reference and treatment periods. Because the same adult females occurred in multiple samples across periods, we modeled mean period parturition rate by using the generalized linear mixed model procedure with the binomial distribution and logit link (PROC GLIMMIX) in

SAS where the period was the fixed effect and individual puma was the random effect.

We quantified birth intervals for adult females that we could monitor continuously by radio-telemetry. To examine variation in birth interval lengths in the reference and treatment periods, we used data from all mothers in the study except those that we knew had lost all of the cubs in their previous litter. We used individual, study period (i.e., reference, treatment), and birth interval length in months as covariates. Because some adult females occurred in multiple intervals and both periods, we analyzed birth interval as the response variable with the mixed linear model procedure (PROC MIXED) in SAS, with period as the fixed effect and individual puma as the random effect.

We examined litters at nurseries when the cubs were 25–45 days old. If younger cubs died before we observed them, then the litter sizes we recorded might be biased low. We coded the data by adult female, study period, and the number of cubs observed (i.e., 1, 2, 3, 4). Adult females in the samples gave birth multiple times within the same period and in both periods; therefore, we modeled period mean litter size using the mixed linear model procedure (PROC MIXED) in SAS, where period was the fixed effect and individual puma was the random effect. We used a normal distribution error structure for this analysis and assumptions of normality were met. We examined the proportions of male and female nurslings we observed in litters in each study period and the entire study by calculating the binomial proportions and Clopper-Pearson exact 95% confidence intervals by using the PROC FREQ procedure in SAS. We made inferences on period effects on parturition rate (on the logit scale), birth interval, litter size, and proportions of the sexes in litters by examining the 95% confidence intervals on the differences of the estimates for each period by using the delta method (Seber 1982).

Puma hunters.—We compiled data from the surveys returned by hunters. We report ranges and medians for repetitious response values (e.g., number of days hunted). Estimates on number of actual hunters on the study area each treatment year were the number of people requesting permits to hunt UPSA multiplied by the proportion of those that indicated they hunted on UPSA. We report as male:female ratios the number of independent pumas of each sex making tracks <1 day old when first encountered by hunters and researchers, killed and caught and released by hunters, and that were in the LP estimates pre-harvest and post-harvest for each treatment year. We used the ratios to discern risk to pumas of either sex to detection and evidence of selection by hunters.

RESULTS

Puma Capture

From 2 December 2004 to 30 October 2014, we captured as many as 256 pumas a total of 440 times on the UPSA. We considered about 30 individuals to be captured with dogs but we did not handle or mark them at that time because of their dangerous positions in trees or on cliffs. Of those, 11 were in the reference period, of which 6 were associated with marked family members (i.e., mothers or siblings). In the treatment period, we did not handle 19 captured pumas, and 8 of those were

associated with marked family members. It is possible, however, that we captured and marked some of those individuals at later dates in the study, which would reduce the total number of pumas we captured. The number of days we spent each winter searching for pumas with dogs was similar in each period (reference mean = 77, range = 71–82; treatment mean = 79, range = 74–86). However, in RY5 (i.e., 2008–2009) a Colorado state government-mandated hiring freeze resulted in insufficient personnel for thorough searches of the study area and a sub-standard effort to detect pumas. No adults or subadults died from capture procedures. One cub was killed by our tracking dogs. Three cubs died as a result of premature expansions of the radio-collars: 1 nursing starved because the transmitter was caught in its mouth and 2 cubs died after they passed a foreleg through the collar, causing one to starve because it could not keep up with movements of its family, and the other to die apparently of infection after the collar material cut into the axilla.

We uniquely marked 226 pumas, 110 in the reference period and 116 in the treatment period. The number of radio-collared animals monitored each year ranged from 16 to 56 and averaged 40. Marked pumas provided known-fate data on 75 adults, 75 subadults, and 118 cubs. Some cubs and subadults transitioned to older stages, which is why the total of marked individuals in the life stage classes (268) is greater than the total of uniquely marked pumas. By the end of the study, we accounted for the fates (i.e., either survived or died) of all of the radio-collared adults, including those with failed radio-collars, except for 1 female and 1 male. We lost track of the female in TY2 when her collar stopped functioning while she was in a part of her home range outside the UPSA. We lost track of the male when his collar stopped functioning in TY5.

Causes of Mortality in Independent Pumas

In the reference period, the hunting closure on the UPSA and protection of marked pumas in adjacent GMUs to the north effectively eliminated hunting mortality in marked adults of both sexes and subadult females (Fig. 3A). One subadult male was harvested in a GMU adjacent to the UPSA. Over twice as many adults died of natural causes (i.e., intraspecific killing, other causes) than adults that died from human causes (i.e., vehicle strikes, depredation control). Intraspecific killing was the major single cause of death for adults, with 3 times as many females than males. A majority (i.e., 6 of 10) of the independent pumas that died were adult females, with the remainder composed of adult males and subadults. Two subadult female deaths occurred, 1 each from a vehicle strike and trampling by an elk.

In the treatment period, human-causes, hunting in particular, were the most important sources of death for marked adults and subadults, comprising 65% and 100% of adult female and male mortalities, respectively, and 75% of both subadult female and male mortalities (Fig. 3B). Adult females in particular (i.e., 35% of their deaths), and to a lesser extent subadults, continued to die of natural causes. An 11-year-old female that died of starvation apparently in association with senescence was the only independent puma we found that succumbed to that cause during our entire study.

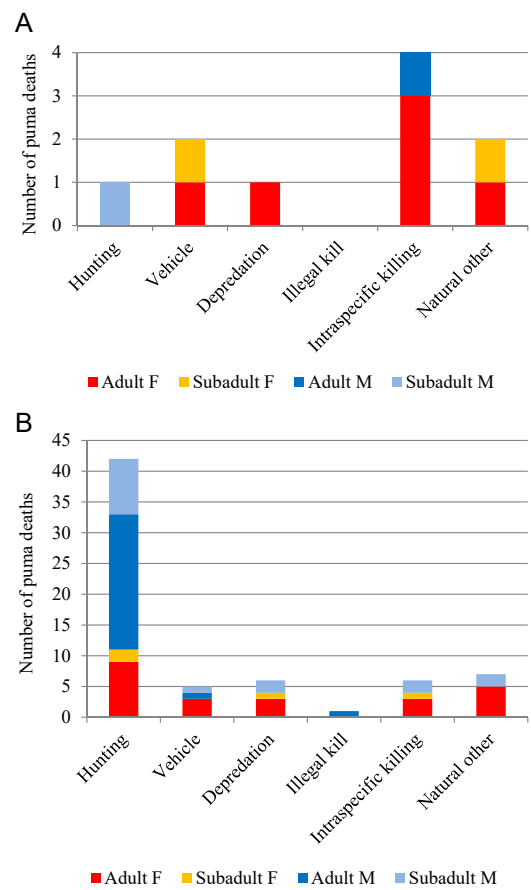

Figure 3. Proximate causes of death in marked adult and subadult female (F) and male (M) pumas during the reference period (A) and the treatment period (B), 2004–2014, Uncompahgre Plateau Study Area Colorado, USA.

Hunting Treatment and Other Mortality

A harvest quota of 8 pumas on the UPSA during TY1–TY3 resulted in 9 animals harvested in TY1 and 8 harvested in each season TY2 and TY3 (Table 1). Harvest rates based on the LP \hat{N}_t estimates (Table 2) of independent pumas on the UPSA for years TY1–TY3 averaged 16% (Table 3). After we reduced the quota to 5 pumas for TY4 and TY5, hunters killed 5 animals in each of those seasons. In TY4 and TY5, UPSA-specific harvest rates averaged 13%. Males comprised 69% and adult males 46% of the total 35 pumas harvested on the UPSA during TY1–TY5. Females comprised 31% and adult females 23% of the total harvest. The average estimated age of all the pumas harvested on

Table 3. Puma mortality rates based on adult and subadult pumas that died on the Uncompahgre Plateau Study Area (UPSA) and with additional adult and subadult pumas with home ranges that overlapped the UPSA that died on adjacent Game Management Units (in parentheses) expressed as a proportion of Lincoln-Petersen abundance estimates (\hat{N}_c) during hunting seasons from treatment year 1 (TY1) to treatment year 5 (TY5), 2009–2014, Colorado, USA.

Treatment year	Puma harvest rate	Total human-caused puma mortality rate	Total puma mortality rate
TY1	0.16 (0.25)	0.16 (0.25)	0.16 (0.25)
TY2	0.14 (0.16)	0.18 (0.20)	0.18 (0.20)
TY3	0.18 (0.23)	0.18 (0.23)	0.23 (0.27)
TY4	0.12 (0.19)	0.12 (0.19)	0.14 (0.21)
TY5	0.14	0.14	0.16

the UPSA during the treatment period was 3.5 years (range = 1.1–9.5).

Six other independent pumas died of causes other than hunting on the UPSA during the hunting seasons, ranging from 0–2 deaths each season; all were adult females (Table 4). With these deaths added to the harvest on the UPSA, total mortality rates during TY1–TY3 averaged 19% (Table 3). In TY4 and TY5 total UPSA mortality rates averaged 15%. However, 4 of the 6 adult females died of natural causes on the UPSA. Just counting the human-caused deaths on UPSA that would have

Figure 4. The age structure of pumas harvested on the Uncompahgre Plateau Study Area (UPSA) and with home ranges overlapping the UPSA that were harvested on adjacent Game Management Units, 2009–2014, Colorado, USA.

been detected by wildlife managers (i.e., harvest and depredation control), the total UPSA human-caused mortality during TY1–TY3 averaged 17%. In TY4 and TY5 the total UPSA human-caused mortality rate averaged 13%.

In addition, hunters killed 11 other radio-collared independent pumas (2 adult females, 8 adult males, 1 subadult female) in adjacent GMUs 61, 62, 65, and 70 that had home ranges overlapping the UPSA boundaries (Table 4). Two of the adult radio-collared males were trailed by hunters' dogs off of the UPSA and were caught and killed in adjacent GMUs 65 and 70. Including these pumas, harvest rates as a percentage of the LP \hat{N}_c estimates averaged 21% for TY1–TY3 and 17% in TY4 and TY5. Also, when including these cases, total human-caused mortality (range = 19–25%) and total mortality rates (range = 21–27%) increased during TY1–TY4 but not in TY5 (Table 3). Of the 46 pumas that used the UPSA and were harvested during TY1–TY5, males comprised 70% and adult males 53%. Females comprised 30% and adult females 22% of the total harvest. The average estimated age of all the pumas harvested was 3.8 years (range = 1.1–10.1). Of those, 26% were subadults, 48% were adults >2–5 years old, and 26% were adults >5 years old (Fig. 4).

All marked adults that died from hunting (9 females, 22 males) and depredation control (3 females) were detected by, or reported to, wildlife managers. However, 18 adult deaths, including 15 natural (14 females, 1 male), an illegal kill (1 male), and 2 (both females) of the 4 vehicle strikes (3 females, 1 male) were not detected by wildlife managers but instead by our radio-telemetry monitoring. All marked subadult deaths from hunting (2 females, 10 males), depredation control (1 female, 2 males), and vehicle strikes (1 female, 1 male) were detected by, or reported to, managers. But managers detected only 1 (male) of 6 subadult deaths (2 females, 4 males) due to natural causes.

Table 4. Adult and subadult pumas that died of all causes on the Uncompahgre Plateau Study Area (UPSA) and adult and subadult pumas with home ranges that overlapped the UPSA that died on adjacent Game Management Units (in parentheses) during hunting seasons from treatment year 1 (TY1) to treatment year 5 (TY5), 2009–2014, Colorado, USA.

Treatment year	Hunting	Vehicle strike	Depredation control	Natural	Total mortalities

TY5	5	0	0	1	6

Table 5. Mortality causes and number and percentage of deaths by sex and total by period of radio-collared puma cubs during the reference ($n = 28$ female, 27 male) and treatment ($n = 27$ female, 36 male) periods, 2004–2014, Uncompahgre Plateau Study Area, Colorado, USA.

Study period	Mortality cause	Female deaths (%)	Male deaths (%)	Total deaths (%)
Reference	Infanticide	9 (64.3)	4 (100)	13 (72.2)
	Predation	1 (7.1)	0 (0)	1 (5.6)
	Unknown natural	3 (21.4)	0 (0)	3 (16.7)
	Vehicle strike	1 (7.1)	0 (0)	1 (5.6)
Treatment	Infanticide	3 (30)	5 (29.4)	8 (29.6)
	Unknown natural	0 (0)	4 (23.5)	4 (14.8)
	Natural starvation	1 (10)	2 (11.8)	3 (11.1)
	Human-caused starvation	4 (40)	2 (11.8)	6 (22.2)
	Vehicle strike	0 (0)	2 (11.8)	2 (7.4)
	Depredation control	2 (20)	1 (5.9)	3 (11.1)
	Mauled by hunter's dogs	0 (0)	1 (5.9)	1 (3.7)

Of 55 radio-collared cubs (28 females, 27 males) monitored in the reference period, 18 died (Table 5). Of those, 72% died when ≤ 5 months old. Natural causes dominated deaths of cubs (94.4%), of which infanticide was the greatest single cause (72.2%). One cub was killed by a vehicle strike. Four non-collared cubs also died, including 1 litter of 3 nurslings that starved to death after the mother was killed for depredation control, and 1 ear-tagged cub that died of infanticide when the mother was also killed by a male puma.

Of the 63 radio-collared cubs (27 females, 36 males) monitored in the treatment period, 27 died (Table 5). Of those, 80% died when ≤ 5 months old. Natural mortality comprised the majority of cub deaths (55.6%). The greatest proximate mortality cause was starvation including 3 cubs of 2 mothers that died of natural causes, 3 cubs of 2 mothers killed by hunters, and 3 cubs of 1 mother killed for depredation control. The 6 cubs that starved because their mothers died from anthropogenic causes comprised 22.2% of mortality during the treatment period. Infanticide deaths declined from 72.2% to 29.6%, and human-caused deaths increased from 5.6% to 44.4% from the reference period to the treatment period. In addition, we observed mortality in 3 litters of non-collared cubs: 2 litters (1 with 2 cubs and 1 with ≥ 1 cub) died of infanticide, and the third litter (with ≥ 1 cub) died because of black bear predation.

Infanticide caused 13 cub deaths in 8 of 32 radio-monitored litters in the reference period. This included 1 litter of 3 cubs killed 1–8 days after the mother was killed by vehicle strike. In the treatment period, 8 cubs in 5 of 45 radio-monitored litters died of infanticide. The proportion of litters subject to infanticide in the reference period tended to be higher (0.25, 95% CI = 0.12–0.43) than in the treatment period (0.11, 95% CI = 0.04–0.24), but the 95% confidence intervals (–0.04–0.32) on the difference included zero.

Abundance, Population Growth, and Mortality in Independent Pumas

The LP \hat{N}_t estimates of independent pumas that used the UPSA increased in the reference period from 23 in RY2 to 57 in TY1

Figure 5. Lincoln-Petersen estimates (dots) with 95% confidence intervals (bars) of independent pumas that used the Uncompahgre Plateau Study Area each winter, reference year 2 (RY2) to treatment year 5 (TY5), 2005–2014, Colorado, USA.

(Table 2; Fig. 5) at median observed finite growth rates (λ) ranging from 1.04 (RY3–RY4) to 1.39 (RY2–RY3 and RY5–TY1; Table 6). In the treatment period, estimated abundance of independent pumas on the UPSA declined from 57 in TY1 to 37 in TY5. The geometric mean of λ showed an average 10% decline in abundance each year. Non-marked pumas captured for the first time or harvested when ≥ 3 years old and used to adjust n_2 data in previous years for LP estimates included 11 females (average age = 4.5 yr, 95% CI = 3.5–5.5) and 13 males (average age = 3.8 yr, 95% CI = 3.3–4.3).

Estimated abundance of independent pumas that ranged on the UPSA declined 23% between TY1 and TY3 (Table 2) after an average 15% harvest on the UPSA in TY1 and TY2 (Table 3; Fig. 5). In total, estimates of independent pumas that ranged on the UPSA declined 35% by TY5 following 4 hunting seasons (TY1–TY4) in which annual harvest rates averaged 15%. For the population declines measured by TY3 and TY5 where the TY1 95% confidence interval on the estimate does not overlap with the interval of TY3, the first indicated decline, and the interval for TY5, the last year, the total human-caused mortality rates on the UPSA averaged 17% and 16%, respectively. Likewise, the UPSA total mortality rates averaged 19% and 18%, respectively. Including the radio-collared pumas with home ranges overlapping the UPSA that were harvested on adjacent

Table 6. Estimated finite growth rates (λ) and lower and upper 95% confidence limits (LCL, UCL) of independent puma abundance, reference years 2–5 (RY2–RY5) and treatment years 1–5 (TY1–TY5), 2005–2014, based on Lincoln-Petersen estimates (N_t) of independent pumas in winter, Uncompahgre Plateau Study Area, Colorado, USA.

Interval	λ		
	Median	95% LCL	95% UCL

TY4–TY5	0.87	0.74	1.02

GMUs, harvest rates averaged 21% during TY1–TY4 (Table 3). For the population declines measured by TY3 and TY5, the total human-caused mortality rates on the UPSA averaged 23% and 22%, respectively, and the UPSA total mortality rates averaged 24% and 23%, respectively.

Our multinomial analysis of fates of marked independent pumas at the population scale included 19–44 individuals annually from RY2–RY5 and 39–50 annually TY1–TY5 (Fig. 6A). Of those, 35 females and 42 males died, including 11 females and 33 males that were harvested, all of them in the UPSA and 4 bordering management units (i.e., GMUs 61, 62, 65, 70) managed for stable or increasing puma population objectives (Fig. 7). Only 1 of the marked independent pumas with known fates was harvested during the reference period, a subadult male killed in a GMU adjacent to the UPSA in RY5. In contrast, annual harvest rates in the treatment period ranged from 13–27% (Table 7). Population-level harvest rates for years TY1–TY4 averaged 22% (Table 7), and preceded the 35% reduction in the estimated abundance of independent pumas on the UPSA by TY5. Females and adult females comprised 26% and 21%, respectively, of the total number of marked pumas harvested during TY1–TY5. Other human-caused mortality averaged 2% annually in the reference period and 5% annually in the treatment period. Total annual human-caused mortality rates averaged 3% in the reference period and increased to 25% in the treatment period. Average annual natural mortality rates

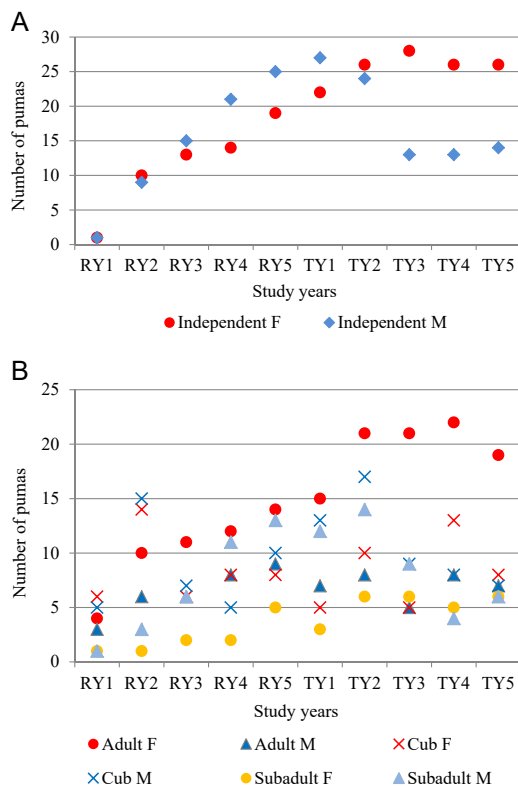

Figure 6. Numbers of marked independent (i.e., adults and subadults) female (F) and male (M) pumas for multinomial analysis of cause-specific mortality rates (A), and adult, subadult, and cub pumas for survival rate estimates (B), reference year 1 to treatment year 5 (RY1–TY5), 2004–2014, on the Uncompahgre Plateau Study Area and bordering Game Management Units, Colorado, USA.

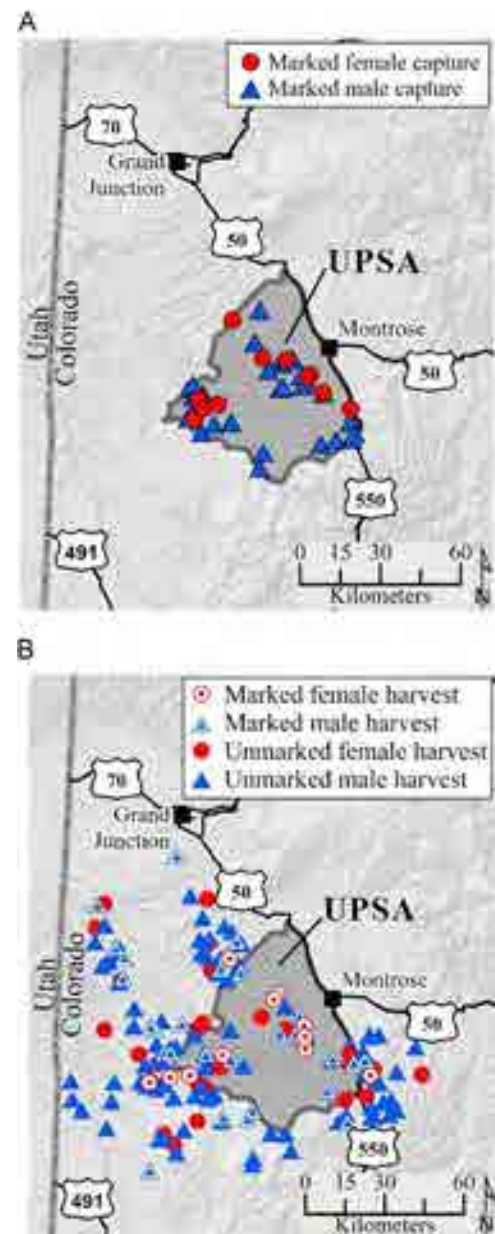

Figure 7. Initial capture locations of marked independent pumas (A), and harvest locations of marked and unmarked independent pumas (B) that were either harvested on the Uncompahgre Plateau Study Area (UPSA) or adjacent Game Management Units during the treatment period, 2009–2014, Uncompahgre Plateau, Colorado, USA.

were low in both the reference and the treatment periods (5%, 6%, respectively). Total annual mortality rates averaged 8% in the reference period and increased to 31% in the treatment period. The average annual population-scale emigration rate (i.e., from the UPSA and adjacent GMUs) was similar in the reference and treatment periods (8%, 4%, respectively).

Sex and Age Structure

The sex and age structure on the UPSA in winter, based on LP estimates of adult females, males, and subadults indicated that adults were more abundant than subadults every year (Table 8). In the reference period, adult females were in parity with adult males during RY2–RY3 when the abundance of independent

Table 7. Population-scale estimated puma agent-specific mortality rates and emigration rates (with 95% CIs) for marked adult and subadult pumas with known fates from multinomial analysis of reference years 2–5 (RY2–RY5) and treatment years 1–5 (TY1–TY5), 2005–2014, Uncompahgre Plateau Study Area and adjacent Game Management Units, Colorado, USA.

Study year	Hunting mortality	Other human-caused mortality	Natural mortality	Population-scale emigration ^a	Total human-caused mortality	Total mortality

^a Population-scale emigration rates refer to marked subadult pumas that moved beyond the boundaries of the Uncompahgre Plateau Study Area and bordering Game Management Units.

pumas was lowest. As the abundance of adults increased to the beginning of TY1, adult females became more numerous than adult males by ratios ranging from 1.2:1–1.9:1. During the treatment period, ratios of adult females to males diverged further, ranging from 1.2:1–3:1, with the widest margins during TY3–TY5 when the population declined again to a low phase. Subadult females occurred slightly more than males (i.e., 29 females: 25 males; Fig. 8) throughout the study. Cubs outnumbered subadults every year, and generally numbered less than adults (Table 8).

During the reference period, we found relatively few pumas 1–2 years old of which there were over twice as many females as males (Fig. 8). In the first 2 years of the reference period, adults >5 years old were few (Fig. 8). The number of pumas >5 years old increased, however, during RY3 to the beginning of TY1 as the population on the UPSA increased.

The broadest age distribution for both sexes occurred at the start of the treatment period and after 5 years of no hunting (i.e., TY1; Fig. 8). Pumas 1–5 years old comprised 66% of the independent animals; the other 34% were adult females and males >5 years old (Fig. 8). In TY1, adult males >5 years old comprised 43% of that segment of the population. Estimated winter

abundance of adult males declined by 59% between TY1 and TY4 and remained as low in TY5 (Table 8). After 2 years of hunting, adult males >6 years old were absent from the sampled winter sex and age structures (TY3–TY5; Fig. 8D). There were more pumas 1–2 years old tallied each year in the treatment period than each year in the reference period. Also, there were almost as many females (21) as males (23) 1–2 years old throughout the treatment period.

Estimated adult female abundance was generally stable from TY1–TY4 but declined to its lowest in TY5 (Table 8). The difference in the TY4 and TY5 adult female estimates could mostly be explained by 5 adult females that died during TY4 (2 harvested on the UPSA, 1 harvested adjacent to the UPSA, 1 died of natural cause, 1 died of vehicle strike) and 1 adult female that stayed on a portion of her home range outside the UPSA after June in TY4. In addition, 2 adult females caught in TY5 with home ranges that overlapped the UPSA were back-aged into the TY4 estimate. We could not directly account for other non-marked adult females estimated in TY4 that might have died before TY5 or had overlapping home ranges with the UPSA. Adult female age distribution was relatively even from TY1–TY3; but adult females >6 years old declined during TY4 and TY5 (Fig. 8C).

At the beginning of RY1, independent males averaged 2.7 years old (95% CI = 1.8–3.7). Similarly, independent females averaged 3.3 years old (95% CI = 2.3–4.2). By the beginning of TY1, independent males averaged 4.2 years old (95% CI = 3.1–5.2), similar to the average of 4.4 years for independent females (95% CI = 3.4–5.3). By the start of TY5 the average age of independent males was 2.9 years old (95% CI = 2.1–3.7), indicative of the declining male age structure. Independent females at the start of TY5 averaged 4.5 years old (95% CI = 3.3–5.7), similar to TY1.

Philopatry, Dispersal, and Emigration

We estimated age (months) of transition from the cub to subadult stage for 15 radio-collared pumas (11 males, 4 females). They became independent at a median age of 13.0 months (\bar{x} = 13.7 months, range = 9–16). Ten pumas (8 males, 2 females) dispersed from natal areas at a median age of 14.5 months (\bar{x} = 15.5 months, range = 10–22) and during April to October. Seven of those (5 males, 2 females) dispersed from natal areas

Table 8. Lincoln-Petersen winter estimates and 95% confidence intervals of adult female, adult male, and subadult (sexes combined) pumas, and counts of cubs (sexes combined), reference years 2–5 (RY2–RY5) and treatment years 1–5 (TY1–TY5), 2005–2014, Uncompahgre Plateau Study Area, Colorado, USA.

Study year ^a	Adult females	95% CI	Adult males	95% CI	Subadults	95% CI	Cubs ^b
